Relationship between Trendelenburg tilt and internal jugular vein diameter

S Clenaghan, R E McLaughlin, C Martyn, S McGovern, J Bowra

METHOD

A statistical analysis before the study predicted that 20 subjects would be required for sufficient power, and compared favourably with other similar studies. The procedure was carried out by a single examiner (SC) using healthy volunteers selected at random. The subjects had no history of neck problems or previous IJV cannulation.

Each subject was placed supine on a tilt table, with an inbuilt clinometer that was raised and lowered on an electric motor. The level of the cricoid cartilage was marked and the right IJV was identified using real-time ultrasound (Medison 128 BW high frequency linear probe). Lateral IJV diameter was measured at this level over three respiratory cycles and the maximum diameter was recorded prior to tilt. The subject then was tilted to 10°, 15°, 20°, 25°, and 30° Trendelenburg. For each angle, subjects were kept in position for 30 seconds prior to further measurement of maximum IJV diameter (again over three respiratory cycles) and then returned to the supine position before being placed in the next angle. The actual order of angles was randomly allocated for each subject using a balanced randomisation table, so that we could analyse the effects of prior angle and cumulative tilt.

RESULTS

We recruited a total of 20 subjects (10 men, 10 women; age range 22–57 years). Clear ultrasound images were obtained and no anatomical anomalies were encountered.

The mean supine IJV diameter ranged from 13.5 mm at 0° tilt to 16.7 mm at 25° tilt (table 1, fig 1). Mean IJV diameter increased significantly at 10° tilt. There was a non-significant trend to increased diameter with greater angles of tilt, with a maximum at 25°.

DISCUSSION

In the ED, patients who require emergent central venous cannulation are those in need of rapid infusion of fluids or drugs, or monitoring of central venous pressure because of cardiovascular instability. Cannulation in such patients is often difficult (for example, due to intravascular depletion) and may have an increased risk of complications such as failed cannulation, arterial puncture, haematoma, and pneumothorax.

In this context, institutions such as NICE recommend ultrasound guidance for central vein cannulation in order to improve the chance of successful cannulation. While 25° achieved optimum distension, this may not be practical and may be detrimental (for example, risk of raised intracranial pressure).

Abbreviations: ED, emergency department; IJV, internal jugular vein; NICE, National Institute for Clinical Excellence
was no benefit in tilting the patient to a steeper angle prior to settling at a lesser angle to carry out the procedure. There did not appear to be any “stretching” of the IJV to allow greater distension at a lesser angle.

Trendelenburg tilt is used in IJV cannulation to optimise conditions for successful cannulation. Our results show that IJV distension shows marked inter-subject variability and that minimal increases in diameter may occur. Although this may be statistically significant, is it clinically significant? It is difficult to say. This study was not designed to assess the success of cannulation, but it highlights a significant problem with blind cannulation in that we do not know, in an individual patient, how the IJV will respond. What we can do is provide optimum conditions to facilitate cannulation.

We recommend that practitioners use 10° of tilt when attempting central venous cannulation in the absence of real time ultrasound. However this technique assumes normal anatomy and therefore real time ultrasound is preferable.
