ABSTRACT

Introduction Improved early pain control may affect the longer-term prevalence of persistent pain. In a previous randomised, controlled trial, we found that the administration of ketamine on hospital arrival decreased pain scores to a greater extent than morphine alone in patients with prehospital traumatic pain. In this follow-up study, we sought to determine the prevalence of persistent pain and whether there were differences in patients who received ketamine or morphine.

Methods This study was a long-term follow-up study of the prehospital, prospective, randomised, controlled, open-label study comparing ketamine with morphine in patients with trauma and a verbal pain score of >5 after 5 mg intravenous morphine. Patients were followed-up by telephone 6–12 months after enrolment, and a questionnaire including the SF-36 (V.2) health-related quality of life survey and the Verbal Numerical Rating Scale for pain was administered.

Results A total of 97/135 (72%) patients were able to be followed-up 6–12 months after enrolment between July 2008 and July 2010. Overall, 44/97 (45%) participants reported persistent pain related to their injury, with 3/97 (3%) reporting persistent severe pain. The prevalence of persistent pain was the same between study groups (22/50 (44%) for the ketamine group vs 22/47 (46%) for the morphine group). There was no difference in the SF-36 scores between study arms.

Conclusions There is a high incidence of persistent pain after traumatic injury, even in patients with relatively minor severity of injury. Although decreased pain scores at hospital arrival are achieved with ketamine compared with morphine, this difference does not affect the prevalence of persistent pain or health-related quality of life 6 months after injury. Further larger studies are required to confirm this finding.

Trial Registration Number Australian and New Zealand Clinical Trials Registry (ACTRN12607000441415).

INTRODUCTION

Acute pain is a common presentation to healthcare clinicians,^{1–4} and is a significant contributor to disability many months, or years, after injury. The effective management of pain is obviously of critical importance in the short term, yet the effectiveness of early pain management may also be associated with the likelihood of persistent pain syndromes and the pain-related anxiety and distress that follow.^{5–8} One of the theories postulated for the progression of acute to persistent pain is central

sensitisation, whereby nociceptive neurons increase their response to non-painful stimuli, develop spontaneous activity, and broaden the area of the body that is involved with the pain over time.⁹ Persistent pain significantly affects people's physical and mental health,^{5–8} and can delay functional recovery after traumatic injury.^{10–11} The prevalence of persistent pain after injury has been reported to be 11–67%,^{12–15} and it adversely affects health-related quality of life.

Most acute traumatic pain management studies focus on efficient reduction of pain during the episode of care, but few studies follow patients over the medium to long term after injury. The aim of this study was to determine the prevalence of persistent pain and self-reported health-related quality of life outcomes 6–12 months after injury and enrolment in a prospective randomised controlled study that compared the effectiveness of morphine with morphine and ketamine in patients with moderate to severe traumatic pain before arrival at hospital.

METHODS

The setting and study design of the morphine and ketamine versus morphine alone randomised controlled trial has been previously described.¹⁶ Briefly, patients with trauma and a verbal pain score of >5 after 5 mg intravenous morphine were eligible for enrolment. Those with any of the following were excluded: known allergy to ketamine hydrochloride or morphine sulfate, pregnant or lactating women, ischaemic chest pain, acute pulmonary oedema, and/or severe hypertension (systolic blood pressure >180 mm Hg), head injury with history of loss of consciousness or Glasgow Coma Score <15, no venous access available, or presumed intoxication with alcohol or illicit substance. Patients allocated to ketamine received a bolus of 20 mg followed by 10 mg every 3 min. Patients allocated to morphine alone received up to 5 mg intravenously every 5 min until pain free (standard care). Pain scores were measured at baseline and at hospital arrival.

Patients were then followed-up via a telephone interview 6–12 months after enrolment into the study. Two instruments were administered to participants enrolled in this study to measure both the presence of persistent pain and health-related quality of life: the Short Form 36 V.2 Health Survey (SF-36; QualityMetric, Lincoln, Rhode Island, USA)¹⁷ and a global pain numerical rating

score. The SF-36 was divided into two aggregate summary measures: the Physical Component Summary (PCS) and the Mental Component Summary (MCS).¹⁷ The global pain measure used the Verbal Numerical Rating Scale (VNRS)¹⁸ and reported the patient's self-rated current pain at the time of the interview. Patients were asked to rate their current pain intensity using an 11 point scale 0–10 (0 being 'no pain' and 10 being 'worst pain ever experienced').

Participants were eligible if they had been recruited for the ketamine study.¹⁶ Each participant was contacted by telephone 1 month after enrolment to obtain consent for access to their medical record from the receiving hospital and for a follow-up telephone call for the purpose of conducting the questionnaire. Participants were contacted via the landline or mobile phone number recorded on the case report form at the time of enrolment. If the participant was not contactable via the phone numbers provided at enrolment (ie, phone numbers disconnected, not responding to messages left on answering machines, no answer, and wrong numbers) after at least five attempts, additional sources were used to identify current contact details. These sources included the Whitepages, the patient's medical discharge summary (where available), and the ambulance service patient database. The telephone interview took ~20 min to complete, and each participant was offered the opportunity to ask questions about the study and their participation. Several trained interviewers conducted the telephone interviews, and each was blinded to the trial arm allocation of the participant at the time of the interview. Owing to the method of SF-36 administration (telephone interview), there were no missing data. Only one person contacted for follow-up interview refused to take part in the SF-36.

Statistical analysis

The sample size calculation has been provided previously,¹⁶ and was powered to detect a difference in the primary outcome measure (change in VNRS score), not the secondary outcome measures, which include the long-term outcomes. Transformation of raw scores was performed using Stata V.11 using the published Australian and New Zealand population norms.¹⁹ The baseline characteristics and SF-36 summary and scale scores were compared using the two-sample t test for continuous variables. The global pain scale scores were compared using the two-sample Wilcoxon rank-sum test, as these data were not normally distributed. Treatment effects were tested at a two-sided significance level of 0.05.

RESULTS

A total of 136 participants with moderate to severe traumatic pain were enrolled between December 2007 and July 2010 (a 30-month period). Follow-up of participants continued until December 2010. One person withdrew consent to participate in the trial, leaving 135 participants eligible for analysis. Sixty-five (48%) participants were randomly assigned to the morphine-only group (M group) and 70 (52%) to the ketamine plus morphine group (K+M group). The baseline characteristics were similar between the two groups and are shown in table 1.

Study participants could be followed-up in 72% of cases (97/135). Thirty-seven participants (27%) were unable to be contacted by phone, and one participant (1%) refused to participate in the interview. Of those who were available for follow-up, 48% (47/97) had been enrolled in the ketamine arm and 52% (50/97) in the morphine arm.

*Missing data n=6 (3 from each group).

K+M group, ketamine plus morphine group; M group, morphine-only group.

Responders vs non-responders

Non-responders and responders were very similar with respect to all characteristics, except that non-responders were less likely to be male (50% vs 66%) and were slightly more severely injured (mean Injury Severity Score 6.2 vs 4.0).

Outcomes at follow-up

Table 2 summarises PCS and MCS scores of the 97 participants who were followed-up by participant characteristic.

The overall mean PCS and MCS summary measure scores were the same for the two study groups (table 3).

Overall, 45% (44/97) of participants reported persistent pain related to their injury, with 3% (3/97) reporting persistent severe (VNRS >7) pain. The prevalence of persistent pain was approximately the same in the two study groups (K+M group: 44% (22/50); M group: 46% (22/47)). The self-reported global median pain score at follow-up was no different between the K+M group (0 (IQR 0–2)) and the M group (0 (IQR 0–3)) (Wilcoxon p value=0.44).

DISCUSSION

There was no clinically significant difference in the long-term follow-up between study groups with respect to the summary or global pain score. Even so, this study is important, as it provides information about the long-term evaluation of management of acute pain. Most studies focus only on the immediate effect of the intervention.

There was no difference in the median self-reported global pain scale between the two study groups; however, 45% of participants reported persistent pain as a result of their injury. This finding is particularly important given the relatively minor nature of the injuries sustained, most being isolated musculoskeletal trauma. Early, effective pain management is important for several reasons. First, pain relief after injury is important for humanitarian reasons. Perhaps of equal, or arguably more, importance, earlier and more effective treatment of acute pain may reduce or even terminate the progression from acute to persistent pain.^{10–13} Effective pain management in both the emergency medical services (EMS) and emergency department setting may play a role in reducing the likelihood of chronic

pain syndromes and pain-related anxiety and distress after the acute phase.^{5–8} The phenomenon of the progression of acute pain to chronic pain syndromes is also seen in surgery, where there is strong evidence that some early anaesthetic/analgesic interventions reduce the incidence of chronic pain after surgery.²⁰ Furthermore, persistent pain is a substantial contributor to the burden of disease after injury, significantly impacting on people's physical and mental health,^{5–8} and can delay functional recovery after traumatic injury.^{10–11}

Future pain management research should also aim to follow participants over time to evaluate the effect the interventions have on long-term physical and mental health outcomes and the association of acute pain characteristics and management with the development of persistent pain.

Limitations

A limitation to the analysis of long-term global pain and quality of life of the participants in this study was the loss to follow-up. Follow-up was possible in 72% (97/135) of participants, and it is possible that the inability to locate all study participants may affect the validity of the study's secondary end point—long-term health-related outcome. There was, however, little difference in the characteristics profile of those who responded and those who did not respond. Furthermore, the number of patients included in this phase of the study was moderate, and therefore the power to identify a difference between groups, if one exists, may have been limited. We did not have the 'time to treatment' interval available to us, and we feel that this may have been an important covariate and should be collected and considered for future studies in this area.

Table 3 Summary measures by study group

Characteristic	K+M group (N=50)	M group (N=47)	p Value*
Physical Component Summary	49.0 (11.1)	47.9 (10.9)	0.64
Mental Component Summary	50.0 (12.0)	50.0 (13.2)	0.98

Values are mean (SD).

*Two-sample t test.

K+M group, ketamine plus morphine group; M group, morphine-only group.

Finally, it was not possible to interview all study participants at the same time period after their enrolment. While it was intended to conduct interviews 6 months after enrolment, a number of participants were unable to be contacted until up to 12 months after recruitment.

CONCLUSION

There is a high incidence of persistent pain after traumatic injury, even in patients with relatively minor severity of injury. There was no difference in persistent pain prevalence, global median pain intensity or SF-36 summary measures in this pre-hospital trauma cohort. We feel this study, despite being moderate in size, provides valuable information for researchers aiming to undertake further, larger-scale research in this area of persistent pain mechanisms and aetiology. Furthermore, clinical trials that examine acute pain management interventions should include in their study design medium- to long-term follow-up of health-related quality of life and prevalence of persistent pain.

Acknowledgements The authors would like to acknowledge the contribution of the paramedics from Ambulance Victoria who assisted by enrolling participants and the submission of data.

Contributors PAJ, PC, and SB conceived the study, and PAJ, PC, SB, TW, MF and KM designed the trial. PAJ obtained research funding through a TAC research fellowship. PAJ, PC, SB, TW and KM supervised the conduct of the trial and data collection. PAJ undertook recruitment of participating sites and patients and managed the data, including quality control. DJ provided statistical advice and analysed the data. TW chaired the trial steering committee. PAJ drafted the manuscript, and all authors contributed substantially to its revision. PAJ takes responsibility for the paper as a whole.
