Inadvertent intracranial insertion of a nasogastric tube in a non-trauma patient

R M Freij, S T H Mullett

Abstract
Complications following nasogastric intubation in patients with basal skull fractures are well documented. This report is of a rare cause of inadvertent intracranial placement of a nasogastric (NG) tube in a non-trauma patient. The patient subsequently died. The use of NG tubes, their place in airway management, and lessons to be learned from this case are discussed. (J Accid Emerg Med 1997;14:45-47)

Keywords: nasogastric tube; aspiration; airway; frontal-ethmoidal defect

Case report
A 59 year female patient with a history of known epilepsy presented to our accident and emergency (A&E) department in status epilepticus of six hours’ duration. The fit was terminated on arrival by administering intravenous diazepam. She was resuscitated with high flow oxygen, an oropharyngeal airway was inserted, and intravenous fluids were given. The history obtained from her husband was of several hours vomiting before the fit, but no history of any febrile illness or upper respiratory tract symptoms. She had been epileptic for 12 years, and despite taking vigabatrin (Sabril) and sodium valproate was poorly controlled. Of relevance in her past medical history was that she had suffered from an episode of pneumococcal meningitis before the start of her epilepsy.

On examination she was pyrexial (38.4°C) with a tachycardia of 130 beats/min. There was decreased air entry to the right lung base, consistent with aspiration, later confirmed by chest radiograph. Her Glasgow coma score was between 6 and 10. Further examination revealed no other abnormalities. She was nursed in the recovery position. To reduce the risk of further aspiration the insertion of a nasogastric tube (NG) was

The rather erroneously named nasal gliomas are rare, benign, and thought to represent heterotopic brain tissue displaced during fetal development. They usually present as intranasal masses in infants and children, and are commoner in South East Asia, our patient originating from that area (Branfoot AC, personal communication). However, they may occasionally persist as a small intracranial defect, visible only on magnetic resonance imaging.

We are aware of only one case report of inadvertent intracranial placement of an NG tube in an adult non-trauma patient. That case differed from ours, in that the patient survived, and it was only postulated that the cribriform plate had been thinned by a recent episode of sinusitis, precipitating the complication. There is a case report of intracranial placement of an NG tube in an infant without associated trauma.

The advanced trauma life support course recommends that NG tubes should not be inserted where there is the possibility of a basal skull fracture, and this is borne out by a number of case reports.

The use of NG tubes is under scrutiny in general. They may be a risk factor in aspiration, leading to anaerobic lung infections, and their use after gastrointestinal surgery has been questioned by some investigators.

**CONCLUSION**

Although this case highlights an extremely rare complication of NG tube insertion, certain lessons can be learned. NG tubes have traditionally been used to reduce the risk of aspiration in patients with altered level of consciousness. However, they carry risks—as this case illustrates—and should never be used as a substitute for a cuffed endotracheal tube, which remains the optimum choice for prevention of aspiration. We also feel that previous head trauma or a history of adult onset epilepsy in association with meningitis should alert the clinician to the possibility of a cranial defect. NG tubes should only be used with extreme care.
Traumatic asphyxia in children

Gregor Campbell-Hewson, Conor V Egleston, Andrew R Cope

Abstract
Two cases of traumatic asphyxia in young children are reported. The first was a 2 year old child run over at low speed by the front wheels of a delivery van. He made an uncomplicated recovery. The second child was pinned to the floor by an empty chest of drawers in an unwitnessed accident. He was discovered in cardiac arrest and resuscitation was unsuccessful. The outcome following traumatic asphyxia is a product of duration of compression and the weight involved. Considerable weight can be tolerated for a short period, whereas a comparatively modest weight applied for a longer period may result in death.

(J Accid Emerg Med 1997;14:47–49)

The syndrome of traumatic asphyxia has been reported regularly in medical publications since its initial description by D'Angers Ollivier following his observations on the cadavers of people trampled upon during crowd disturbances in Paris on Bastille day 1837.1 It has been defined as cervico-facial cyanosis, subconjunctival haemorrhage, and cutaneous petechial haemorrhages following thoraco-abdominal compression.2

It was recently brought to prominence by the Hillsborough Stadium disaster where the victims bore some of the stigmata of traumatic asphyxia, although there were marked differences in presentation and outcome.3

The purpose of this paper is to report two cases of traumatic asphyxia in young children which show important and contrasting features of the pathophysiology of this condition, and to review the relevant published reports.

Case 1
The patient, a healthy 2 year old boy, chased a ball onto a road. He fell and his torso was run over by the front wheel of a delivery van (Ford Transit, unladen weight 1533–2075 kg). The van had been driving slowly and stopped before the back wheels had reached the child. He did not lose consciousness and remained motionless under the van on the instructions of his parents.

On arrival in accident and emergency (A&E) he was alert but jittery. His blood pressure was 105/55, pulse 115, respiratory rate 18, and he was well perfused. He complained of abdominal pain which was poorly localised. His facial appearance was striking, with cervico-facial cyanosis and swelling, widespread petechiae, and bilateral subconjunctival haemorrhages (figure). There were no marks of compression on the torso. On fundoscopy there were bilateral retinal haemorrhages and exudates. Otherwise neurological examination was normal. There were no fractures or other abnormalities on radiographs of the skull, cervical spine, or chest. A plain abdominal radiograph showed acute gastric dilatation. He was initially treated with oxygen, intravenous fluids, urinary catheterisation, and insertion of a nasogastric tube to decompress the stomach. Arterial blood gases, haematology, and biochemistry profiles were all normal. A further chest radiograph 18 hours after the accident was also normal. An ultrasound of the abdomen failed to show any abdominal injury. Clinically he made good progress, although his dramatic facial appearance persisted. He was discharged 8 days later, by which time his appearance had almost returned to normal with only the resolving subconjunctival haemorrhages remaining. The main reason for his prolonged inpatient stay was the development of a swinging pyrexia on day 4 caused by an urinary tract infection, presumably secondary to catheteri-
