Under these circumstances a chest x ray is mandatory to exclude a haemothorax. Late clotted haemothorax, once detected, requires an early thoracotomy for complete clearance and best long term results.

Out of hospital cardiac arrest and associated injury

Andrew I Jones, M James Stuart, Alastair J Gray

Abstract

Three patients are described who sustained injuries around the time of a collapse that led to out of hospital cardiac arrest. In this group of patients the importance of taking a complete medical history and recording the circumstances of the syncopal episode cannot be overemphasised. If cardiac output is successfully restored the possibility of occult traumatic injury must be considered in high risk patients.

Keywords: cardiac arrest; resuscitation; occult trauma

In the immediate aftermath of a successfully resuscitated out of hospital cardiac arrest the presence of an injury may easily be overlooked. We present three cases which illustrate this point.

Case 1

A 65 year old male sustained a cardiac arrest in the street. Bystander basic life support was given immediately. The extended trained ambulance crew found him to be in ventricular fibrillation. Defibrillation restored sinus rhythm.

On arrival at the accident and emergency (A&E) department he was drowsy but responding to questions. He remained in sinus rhythm with a systolic blood pressure of 100 mm Hg. He appeared able to move only his shoulder girdle muscles. Bruxing to the forehead was noted.

Radiography of the neck showed advanced ankylosing spondylitis with a fracture-dislocation. He was stabilised on the intensive care unit but he died the following day.

Case 2

A 63 year old male sustained an out of hospital cardiac arrest. A nurse bystander gave basic life support. The attending extended trained ambulance crew found him to be in ventricular fibrillation, and sinus rhythm was rapidly restored by defibrillation. At this stage he was localising to pain and had a Glasgow coma score of 8. Examination at the A&E department showed bruxing of his right temple. Radiography of his skull was normal but in view of his persisting reduced level of consciousness computed tomography was performed and showed frontal and temporal contusions. He was subsequently intubated and admitted to the neurosurgical unit. After 10 days he was discharged home.

Case 3

A 56 year old man suddenly collapsed in the street and was found to be in ventricular fibrillation by the attending ambulance crew. He was immediately cardioverted and cardiac output was restored.

On arrival in the A&E department he was agitated and combative. He was maintaining his own airway and his oxygen saturation was 99% while breathing high flow oxygen. He had...
a heart rate of 150 beats/min with a systolic blood pressure of 90 mm Hg. Blood glucose was 8 mmol/l on bedside testing. Electrocardiography showed a left bundle branch block pattern and a provisional diagnosis of acute myocardial infarction was made. Intravenous diamorphine and diazepam were given as the patient was proving impossible to restrain.

Further examination revealed a ragged occipital laceration, a Glasgow coma score of 7 with equal reactive pupils, and no evidence of a motor deficit. Both plantar responses were noted to be extensor. On questioning his relatives revealed that he had undergone coronary artery bypass surgery 10 years previously and was on long term warfarin treatment.

Since he had evidence of an acute head injury with significantly altered level of consciousness, urgent computed tomography of his head was performed. This revealed an occipital fracture with contra-coup contusion in the right temporoparietal region.

Discussion
Increasing numbers of patients are successfully resuscitated following prehospital cardiac arrest. Aftercare of these patients tends to focus on the medical aspects of the postarrest phase. Associated trauma owing to cardiopulmonary resuscitation is a well recognised phenomenon. Not so well recognised is coincidental injury arising as a result of the sudden syncope and fall seen in cardiac arrest. As seen in these cases, this may cause severe head and neck injury.

It is well recognised that the presence of ankylosing spondylitis predisposes to cervical cord injury after minor trauma. Similar injuries to the cervical cord after apparently minor trauma have also been described in patients with rheumatoid arthritis. This has profound implications for the prehospital and in hospital care of these patients. When sudden syncope and fall occurs in a patient with an “at risk” cervical spine, full neck immobilisation should be applied. Where no past medical history is available and signs of cranial trauma are evident, immobilisation should be applied as a precaution. Removal of this immobilisation should not be attempted until the cervical spine has been cleared by adequate imaging and normal neurological examination.

In the postarrest phase, a persisting obtunded conscious level may be attributed to hypoxic brain injury. Cases 2 and 3 show that signs of cranial trauma should raise the suspicion of direct brain injury, and computed tomography should be done. This is particularly important in patients who are on anticoagulants.

In this group of patients the importance of taking a complete medical history and recording the circumstances of the syncopal episode cannot be over emphasised. If cardiac output is successfully restored the possibility of occult traumatic injury must be considered in high risk patients.

Ectopic pregnancy presenting with obturator nerve pain

Hassan Shaaban Ali

Abstract
A 27 year old woman had a three day history of pain in the cutaneous distribution of the left obturator nerve before she developed the classical picture of ectopic pregnancy with lower abdominal pain and vaginal bleeding. A left tubal pregnancy was subsequently confirmed by laparoscopy. Referred pain along the obturator nerve has been reported in other pelvic conditions, but has not previously been reported as a manifestation of ectopic pregnancy. Ectopic pregnancy may present with a very wide range of signs and symptoms and should be excluded in females of child bearing age with unexplained symptoms including pain anywhere from the shoulder down to the knee.

Keywords: ectopic pregnancy; obturator nerve; referred pain

Case report
A 27 year old woman presented to the accident and emergency (A&E) department with a two day history of pain on the inner aspect of the left thigh, which later radiated to the left groin. There was no history of trauma. She had stopped taking the contraceptive pill one month before and her last menstrual period had been eight weeks ago.

the intensive care unit, and another from the computed tomography scanner to the neurosurgeons in Nottingham.

The fire brigade called and informed us of a fire in the basement under the department. The department was full of smoke and we could not work in it for several hours. Several patients were sent directly to wards and the ambulance service diverted patients to other hospitals. We opened the outpatient department and the day case unit and treated casualties there. This makeshift plan was difficult to implement. A few hours later when the fire was put out and the smoke dispersed, we returned with our patients to an undamaged department.

Before this experience we have had two fires started deliberately by patients in the department—one in a toilet and one in a waiting room. So the possibility of this, or indeed any, emergency department being unable to function for a period of time is always there. Fire is the most likely cause but explosions, building collapse, electrical failure, flooding, and violent affrays are others. (Working in over 20 hospitals over the last 35 years, AF-M has seen all of these, but only the smoke from this fire was serious enough to cause our emergency department to be closed.)

We had no local plan in our hospital to deal with this contingency. We do now have such a plan and I am sure that other hospitals should follow our example to avoid being caught out.

There are no national guidelines for hospitals or accident and emergency departments to close, but the ambulance service has national guidelines for diverting all ambulances to other hospitals in circumstances such as these. This can easily be arranged through your local ambulance service.

A mobile field hospital could in theory be provided by the armed services. This requires quite a fair sized space to set it up. Reliable sources with experience of setting up these hospitals have told us that this takes at least 48 hours. So this is not a "quick" option, but an alternative if the emergency department is out of action.

Foreign body removal from children's noses

Editor—Nasal foreign bodies are a common problem in children attending accident and emergency departments and general practice surgeries. The cooperation required is often not forthcoming as most patients are under 5 years. Instrumentation requiring restraint, sedation, or even general anaesthesia are frequently necessary. This approach may be avoided by using the positive pressure technique described below, which can be used by the parent to quickly and safely remove a nasal foreign body.1

A history is taken from the parent and child to determine the nature of the foreign body and which nostril is involved. If the child is cooperative, the nares can be examined to locate the foreign body but this is not always possible if there is a clear indication of which nostril is involved. Parents are instructed to sit the child on their knee, with the nostril containing the foreign body closest to the parent. The parent should then close the "patent" nostril using a finger and tell the child that they are going to give them "a great big kiss". Parents should then seal their lips around the child's and deliver a short sharp puff of air. The foreign body is usually extruded with one puff. It is worth holding a paper tissue close by as the foreign body is usually well covered with mucus. If this is unsuccessful several more attempts can be made without any harm. Each additional "puff" may dislodge the foreign body a little further.

The author used this technique in over 20 cases with no failures or complications. Various objects including beads, peas, pieces of bread, and even a rabbit dropping have been removed successfully. The time from insertion of the foreign body to removal by the technique does not appear to be a factor.

Despite the simplicity of this technique it seems little used. It is easily taught to parents and can be undertaken in any setting. Use of restraints, anaesthesia, and instrumentation in frightened and distressed children can be avoided.

Alcohol intoxication

Editor—I read with great interest the recent letters by Tovey et al2 and Denning3 regarding the alcohol content of some proprietary paediatric medicines and commercially available mouthwash. Previously I was able to highlight the potential danger to children of perfumed body sprays,4 which commonly have an alcohol content of between 70-80%. A child attended the accident and emergency department having swallowed the contents of a "tangerine dream" perfumed body spray. She was admitted, but fortunately came to no harm. The presentation of this brand of perfumes was extremely suggestive of a soft drink. No warning was displayed on the containers, which could easily be opened by a child. This article was picked up by several newspapers and a parenting magazine. I subsequently noticed that the company selling these products had withdrawn them from their shelves. The enormous power of the media should be harnessed whenever possible in these and similar areas to protect the most vulnerable in society.

Fitness to drive

Editor—Each year there are more than 15 million visits to UK accident and emergency (A&E) departments.1 Many sustain injuries, suffer from medical conditions, or have had drugs administered to them that temporarily impair the patient's ability to drive safely. Yet it is rare to hear discussion of this issue with the patient. A small prospective audit of 21 patients of driving age who were discharged from the department after the application of a limb plaster failed to demonstrate any written advice as to whether they should drive or not.

It is clear that a doctor has a legal duty to warn those patients whose driving may be impaired not to do so and to record this in the notes.2 Patients who fail to take the advice of the doctor will probably invalidate their insurance.3 The responsibility for the provision of advice for this patient group lies with each A&E department. "Suitability to drive" is now covered in the senior house officer teaching programme.
