better if we are to proactively manage this demand to the benefit of the patient, the ambulance service, and the wider NHS.

Inappropriate ambulance usage is a retrospective diagnosis

EDITOR.—In their review of the use of ambulances, Snook et al acknowledge that the vast majority of the existing ambulance literature is based on retrospective assessment of medical need and has been undertaken by clinicians in accident and emergency (A&E) departments after full assessment and diagnosis.1 More useful estimates of the level of inappropriate use of emergency ambulances require information about the reason for the emergency 999 call and an assessment of the patient before the definitive diagnosis is made in A&E.

It has previously been reported that the most common reasons for inappropriate use of an ambulance are the lack of alternative transport and alcohol intoxication.2 Furthermore, ambulance “misuse” has been reported to be more common among nursing home residents3 and by the socially deprived.4

Analysis of the cohort of patients not transported to hospital provides additional information about the reasons why patients not requiring care in an A&E department may call an ambulance. A small audit undertaken by the West Midlands Ambulance Service provides data about patients who were not transported to hospital after a 999 emergency ambulance call. A sample of 100 consecutive report forms, where the patient was not transported, were reviewed. Ambulance patient report forms were analysed from five ambulance stations. These cases were classified according to reason for non-transport. These reasons are summarised in Table 1.

The reasons for non-removal of a patient from the scene were highly variable. They ranged from automatic fire alarm calls where there may be no incident, to the death of a patient, and from refusal of treatment and transport by the patient to successful treatment by the ambulance paramedic (table 1). Those who refused treatment and had minor conditions or no injuries represented 30% of the study population.

Criteria based dispatch (CBD) has been in full operational use in the West Midlands since April 1997. The CBD categorisation of these patients was confirmed. Of the cases not transported from the scene, 37% were category A (immediate life threatening situation requiring urgent assistance, requires rapid on scene assistance), 50% were category B (serious condition that is not immediately life threatening, requires intervention as soon as possible), and 13% category C (non-serious or non-life threatening conditions that require conveyance to hospital). The exclusion of the decreased (need for resuscitation not known until assessment by ambulance crew) still leaves nearly a quarter of cases where maximal resources are deployed and no patient transport was required. More work is needed to determine if CBD could be improved to allow telephone advice rather than dispatch of an ambulance.

On site computed tomography in the district general hospital for severe head injury

EDITOR.—In their article in September Dr MacNamara et al clearly indicate the value of 24 hour computed tomography being available to every major accident and emergency (A&E) department.1 They do not, however, indicate in the article whether their scanner is manned fully for the whole of the 24 hours, neither do they indicate the distance and time they are away from their regional neurosurgical unit, although both of these factors are crucial to the development of safe guidelines or protocols involving the method by which these patients should be handled.

Certainly in most district general hospitals it would be hard financially to justify manning of an scanner over 24 hour a year. In the West Midlands this means that throughout the year when its likely usage for emergencies out of hours would be quite small. Even allowing for the fact that the figures provided in this article do not allow for weekends or bank holidays, etc, as part of the “out of hours” periods (which must take up a fair number of the 83 annual cases scanned between 0900 and 1700), out of hour usage, even with an A&E service dealing with 110000 patients a year, was relatively small. Thus I suspect the majority of the district general hospitals operate an “on call” scanning service out of hours and this inevitably will lead to delay in getting the computed tomography unit manned and thus the scan performed.

In certain cases where there is a clear urgent requirement for neurosurgical intervention, this delay—added on to the travelling time between the A&E department and the neurosurgical centre—could be extremely crucial in determining an outcome.

When a consultant in Wigan (on call computed tomography and between 25 and 40 minutes from the neurosurgical unit) I discussed this matter with our local neurosurgeons and we came to the conclusion that in certain specified cases—where there was clear clinical evidence to indicate the need for urgent neurosurgical intervention, such as of a developing intracranial haematoma—it was far preferable to arrange the transfer (with, of course, all normal precautions to prevent secondary brain injury) direct to the neurosurgical unit without local computed tomography. By this means the neurosurgical unit was able to make arrangements to receive the patient during the period of transfer and were thus in a position to assess the patient immediately on arrival, arrange direct transfer to their scanner, and then to theatre if this was indicated. This could save one hour or more in getting such patients to theatre.

These cases aside I would certainly agree that the main benefit of the local scan transmitted to the neurosurgical centre was in those patients that did not fit these criteria. In these cases many unnecessary transfers of seriously ill patients with non-operable condition were avoided. This does not only involved one transfer but—because of lack of intensive care unit accommodation at the neurosurgical centre—these patients were, after computed tomography at the centre, very often either subsequently sent back for care in our own intensive care unit, or transferred to yet another hospital.

I strongly feel that the adoption of any protocol guideline is a matter of “horses for courses” and, before anyone rushes off to adopt other department’s good ideas, the local factors pertaining to such cases should be taken very carefully into consideration since, as in other fields, a course of action which eminently suits one unit could be the potential source of severe hazard to patients in a different environment.
