Abstract

Objectives—Delays in parenteral antibiotic treatment may contribute to the high mortality in meningococcal disease. This study aimed to record “door to needle” time in children with meningococcal disease before and after the introduction of a specific teaching programme about the disease.

Methods—“Door to needle” time in 33 children with meningococcal disease, admitted June 1995–December 1996, were studied. Regular teaching sessions encouraging prompt treatment were started in January 1997. “Door to needle” time was then studied for 42 children admitted January 1997–December 1998.

Results—More of the second cohort attended accident and emergency (A&E) directly (9 of 33 v 24 of 42; p=0.01) rather than being referred by a GP. Similar proportions received pre-admission antibiotics from a GP (8 of 24 v 5 of 18). Mortality was similar in the two groups (2 of 33 v 5 of 42). “Door to needle” time was significantly shorter in the second cohort in those with a typical rash (median 60 minutes v 18 minutes; p=0.0004). Only 1 of 23 (4%) children in the second cohort with a typical, petechial rash waited more than 60 minutes for antibiotics, compared with 6 of 24 in the first cohort (p=0.06).

Conclusions—Significant improvements in “door to needle” time in meningococcal disease can be achieved when awareness is heightened by regular teaching. Those with a typical, petechial rash can be treated within 60 minutes of arrival. Strategies to improve immediate treatment of meningococcal disease should include education of A&E staff, especially as an increasing proportion of cases present directly to A&E.

Keywords: meningococcal infection; child; antimicrobial therapy

Early recognition and treatment of meningococcal disease is recommended to decrease mortality.1 2 General practitioners (GPs) and accident and emergency (A&E) staff are advised to give parenteral penicillin to cases of suspected meningococcal disease “as soon as the diagnosis is suspected”.1 However pre-admission antibiotics are only given to 30% of those admitted by GPs.3 In urban areas many patients with meningococcal disease present directly to A&E departments.4 The majority of patients will thus have not received parenteral antibiotics before arrival at hospital.

When awareness of meningococcal disease is high, all those with a typical rash receive parenteral antibiotics within one hour of arrival.1 However, in routine practice antibiotics are delayed for more than one hour in 37% of those with a typical rash.4 Delays in antibiotic treatments also occur in 15% of those who die from meningococcal disease and may contribute to the poor outcome.1

The aim of this study was to record “door to needle” time in children with meningococcal disease before and after the introduction of a specific teaching programme about the disease.

Methods

This prospective study included all children seen with meningococcal disease at Birmingham Heartlands and Solihull Trust between June 1995 and December 1998. The Trust has two A&E departments (at Heartlands and Solihull hospitals), but all paediatric admissions are at Heartlands. During the study period all paediatric admissions were initially assessed in A&E at Heartlands. Meningococcal disease was defined using the Meningococcal Disease Surveillance Group criteria. Disease severity was assessed using the Glasgow Meningococcal Septicaemia Prognostic Score.8 “Door to needle” time was defined as the time from the recorded time of arrival at hospital until the parenteral administration of appropriate antibiotics. “Typical rash” was defined as a petechial or purpuric rash on arrival at hospital and excluded children with no rash or maculopapular rashes. Time of administration of antibiotics was determined from GP referral letters, A&E cards, drug charts, case notes or directly from the staff involved.

From January 1997 a regular teaching session about meningococcal disease was given to nurses and doctors in A&E and paediatrics. This was a lecture using slides, which focused on recognition of the rash and the importance of prompt antibiotic treatment. “Door to needle” times, for those with typical rash and those with atypical or no rash, were compared before and after this date.

Results

Seventy five children with meningococcal disease were seen during the study period (69 confirmed microbiologically); seven died. The children’s ages, disease severity and mortality did not differ significantly between the two time periods (table 1). Significantly more children presented directly to A&E, rather than via

their GP in the second time period (table 1). For 45 children the first dose of parenteral antibiotics was given in the A&E department.

In the first time period six (25%) of the 24 with a typical rash, did not receive antibiotics within one hour. This decreased to one (4%) of 23, after regular teaching sessions. “Door to needle” time was significantly shorter in the second cohort in those with a typical rash (median 60 minutes v 18 minutes; p=0.0004) (table 1). “Door to needle” time did not differ between the two cohorts in those presenting with atypical or no rash (table 1).

Discussion

This study shows that increasing awareness of meningococcal disease at our Trust has led to significantly prompter antibiotic treatment for those with a typical rash. The study also shows an increasing proportion of children with meningococcal disease presenting directly to A&E, rather than via their GP. “Door to needle” time only decreased in those with a typical rash. This suggests there was improved recognition of the rash, not of the sick child.

The main strength of this study was that it was prospective, ensuring good case ascertainment and accurate documentation of timing of antibiotics. In retrospective studies it may be difficult to determine when antibiotics were given. A further strength is that teaching about meningococcal disease was done by one person, ensuring a consistent message was given to staff. Awareness of meningococcal disease may also have been increased by a clinical effectiveness initiative studying “door to needle” time for all adults and children with meningococcal disease in Birmingham from July 1997 to June 1998. However, of those cases of meningococcal disease reported to the Department of Health, 23, after regular teaching sessions. “Door to needle” time did not differ between the two cohorts in those presenting with atypical or no rash (table 1). This suggests there was improved awareness of meningococcal disease. The increasing proportion of children presenting directly to A&E means less children have the opportunity to receive pre-admission penicillin. This makes prompt treatment in hospital even more important. Initiatives to increase awareness of meningococcal disease should be considered in all hospitals that see acutely unwell children.

Antibiotic treatment is only the first step in managing meningococcal disease. Assessment of disease severity and treatment of shock or raised intracranial pressure is also required. Delay in these areas of management may also affect outcome. Further studies looking at promptness of resuscitation and increasing awareness of meningococcal disease in other settings is needed. This study found “door to needle” time was unchanged in children with atypical or no rash. This suggests that further education about recognising sick children is needed.

In conclusion, strategies to improve immediate treatment of meningococcal disease should include regular education of both A&E and paediatric nursing and medical staff.

I would like to thank Wendy King for her enthusiasm, encouragement and for arranging many of the teaching sessions, Caroline Park and the other A&E consultants for their support and Alistair Thomson for helpful comments.
