The immediate impact of the availability of general practitioner services on emergency department presentations

**Editor,**—Emergency departments in NSW have been collecting computerised data about the patients they see using the Emergency Department Information System since 1994. It is possible to use these data to investigate the extent to which the availability of general practitioner services varies with the rate of primary care presentations to NSW emergency departments. It might be expected that emergency departments would see more primary care patients on weekdays that were public holidays than weekdays that were not, because general practices are usually closed on public holidays. In Australia primary care patients have been defined by the National Health Strategy as those who could be managed by a well equipped general practitioner in their surgery. The National Health Strategy operationalised this as patients in triage categories 4 and 5, the less acute categories. This approach has been used in this study.

To test this hypothesis logistic regression analyses were used to compare the number of patients seen on weekdays that were public holidays with those seen on weekdays that were not public holidays, controlling for the triage category of the patient, the day of the week, the month of the year and the year and the clustering on the hospital from which the data were obtained. Data from patients in triage categories 4 and 5 were analysed separately from those in triage categories 1 and 2 because it might be argued that any differences detected arose from changes in patient behaviour because of the public holiday rather than differences in the availability of general practice services. It would not be expected that the availability of general practice services would make any difference to the number of patients seen in triage categories 1 and 2 because these patients have major illnesses that need urgent treatment. Therefore, we investigated only the outcome of the process in which the patients were managed in triage categories 4 and 5.

Data were available from over 1.8 million encounters on ordinary weekdays and 93 397 encounters on public holiday weekdays with patients in triage categories 4 and 5 and 158 335 encounters on ordinary weekdays and 6357 encounters on public holiday weekdays with patients in triage categories 1 and 2. No difference was detected between the number of patients in triage categories 1 and 2 seen on public holidays to those seen on working days (p=0.709, OR=0.998, 95% CI 0.986, 1.010), however there was a small but significant increase in the number of patients seen in triage categories 4 and 5 (p<0.0005, OR=1.0199, 95% CI 1.013, 1.027). The sample size used to look for a difference in the number of patients in triage categories 1 and 2 had 99.9% power to detect a difference of the size detected for patients in triage categories 4 and 5.

Findings in Australia suggest that either patients do not perceive emergency department and GPs to be close substitutes and/or that general practice patients are able to defer their requirements for primary care services until they can receive these from a GP. Is this a common experience in other countries?

Pain management

**Editor,**—I read with interest the paper by practice has changed permanently to pain management that outlined some change strategies for a pain protocol implementation. It was unfortunate that the journal did not include a copy of the tritiated IV narcotic policy for readers to assess separately. Novel approaches to improving pain management are always welcome and the author clearly illustrates the failure in emergency department presentations 10 years ago to provide adequate analgesia. It is interesting to note that despite the documented successful implementation of the policy, 10% (5 of 50 who received narcotic analgesia in 1997) of patients still had at least one dose of analgesia intramuscularly.

Many of the changes described in this paper are based on subjective assessment rather than any more robust analyses. The rationale for using a nursing led process seems to have been justified because “it was felt” that they would provide more formal review and assessment, rather than any evidence that the emergency department doctors were unable to do so. In addition the conclusions that the policy is now “everyday practice” with the obvious bias of temporality has been ignored. It may well be that clinical practice has changed in the study emergency department and other departments over time, this has changed in the study emergency department (ED) team to take an honest look at our work practices and environment. It was the team’s assessment that, in our ED, members of the nursing staff had more regular contact with patients as part of scheduled observation that forms part of the nursing process. Doctors, on the other hand, had less regular contact and were often occupied with other duties. While it would be possible to have doctors perform the review and augmentation role, it would have meant a major change in work practice and thus was less likely to be successful. The issue is not one of who performs which steps in the pain management process, rather that all steps are performed consistently in a way that fits well with established work practices. Different departments may well adopt different strategies to achieve this end.

The question of a control group for comparison was carefully considered at the time the process change was being developed. We had considered investigating time to analgesia as a group treated by the ED) team to take an honest look at our work practices and environment. It was the team’s assessment that, in our ED, members of the nursing staff had more regular contact with patients as part of scheduled observation that forms part of the nursing process. Doctors, on the other hand, had less regular contact and were often occupied with other duties. While it would be possible to have doctors perform the review and augmentation role, it would have meant a major change in work practice and thus was less likely to be successful. The issue is not one of who performs which steps in the pain management process, rather that all steps are performed consistently in a way that fits well with established work practices. Different departments may well adopt different strategies to achieve this end.

The question of a control group for comparison was carefully considered at the time the process change was being developed. We had considered investigating time to analgesia as a group treated by the protocol and one that was not, but this was considered unethical in light of our knowledge that previous practices were ineffective. I agree that there may well have been gradual change in analgesia practice between the time periods studied, however the magnitude of change shown in this study is large and is as impressive for patients treated for other painful conditions, such as renal colic.

The question of bias in the matching of subjects is well made. The study aimed to compare two groups with long bone fractures and it was this larger group rather than specific fracture subgroups that was sampled, giving a reasonable match for overall fracture type between the periods as Dr Leman agrees. Only on subgroup analysis was the mismatch for tibial fracture identified—a chance finding appropriate to acknowledge.

That some patients were treated outside the protocol is almost inevitable! For this fracture group the rate of non-compliance (that is, giving intramuscular analgesia) was 5% of patients (5% of those receiving analgesia) for a renal colic group, it was 3% of patients treated. This rate is low compared with other studies that have investigated adherence to protocols in acute medicine.

My aim in reporting the Western Hospital experience in developing a new process for managing pain was to demonstrate that a commitment to improving patient care, an open and honest appraisal of the barriers and a flexible approach to solutions can result in improving innovative process change.

Dr Leman makes several points that I will answer in turn. The process of developing a pain management protocol is a group activity by the ED team to take an honest look at our work practices and environment. It was the team’s assessment that, in our ED, members of the nursing staff had more regular contact with patients as part of scheduled observation that forms part of the nursing process. Doctors, on the other hand, had less regular contact and were often occupied with other duties. While it would be possible to have doctors perform the review and augmentation role, it would have meant a major change in work practice and thus was less likely to be successful. The issue is not one of who performs which steps in the pain management process, rather that all steps are performed consistently in a way that fits well with established work practices. Different departments may well adopt different strategies to achieve this end.

Open chest cardiac compression

EDITOR—I really wonder about the value of Dr Calinas-Correia’s article on thoracotomy and internal cardiac massage for non-shockable arrested patients. It seems to me that the study only proved the futility of attempting resuscitation this way on these patients. Thoracotomy and internal cardiac massage have a place in the moribund patient with a tamponade and/or penetrating heart wound but this is gung-ho in asystole. The ALS algorithm of early BLS and early ALS must remain the mainstay of attempts to salvage these patients with their universally poor prognosis.

JULIAN KENNEDY
Department of Accident and Emergency Medicine, Royal Bournemouth Hospital, Care Park Lane, Bournemouth BH7 7ER, UK

Authors’ reply

EDITOR—Dr Kennedy seems satisfied with what was presented as the “universally poor prognosis” of patients in non-shockable cardiac arrest, and clearly defends the unquestioned maintenance of the management that achieves that same outlook. The rationale for investigating open chest cardiac massage has been presented within the paper. The indications Dr Kennedy recognises are just some of those accepted by those investigating cardio-pulmonary resuscitation. Our study presents seven patients, and to take it as proof of efficacy or futility is obviously inappropriately. However, the presentation of data collected under a realistic scenario of cardiopulmonary resuscitation is important to allow the discussion regarding the feasibility and usefulness of further research. What remains of foremost importance is that no study showed worse outcomes with thoracotomy than with closed chest compressions in this group of patients, in fact the results have been slightly better with open chest cardiac massage, even if the significance is far from established.1,2 Therefore, the use of thoracotomy remains a matter of investigation, and a priori dismissive verdict seems more of an aesthetic nature than evidence based. The very short times from thoracotomy to ROSC in three of seven patients that we present should encourage further research, as they corroborate the experimental data on the better coronary per-fusion obtained with this technique.3

BOOK REVIEWS

This is a major new textbook of emergency medicine first published in 2000. The contributors read like a “Who’s who” of emergency medicine in Australasia—with a few contributions from North America and the UK.

The book is primarily aimed at the emergency medicine trainee—although the wide authorship has allowed the text to become a “snap shot” of current Australasian emergency medicine practice.

The editorial board has adopted a consensus style and approach to the material published. Accordingly extreme views and minority opinions have been excluded. Obvi-ously in order to keep the book to a manageable size certain topics have been kept brief on the premise that these areas are already covered in established texts. The management of trauma is the area most noticeably thin and this is acknowledged by the editors in the preface. The result is a comprehensive textbook covering most areas of current emergency medicine practice with recent references for further reading.

The text is easy to follow as each subject is set out following a template of Essentials, Introduction, Clinical features, Differential diagnosis, Investigations, Management, Prognosis, Disposition, Controversies and Conclusion. This means that for trainees reading the book as part of their medicine study each chapter follows a prescriptive style and the multiple authorship provides credibility rather than confusion. In my view the three column page layout allows for easy scanning of the material without the feeling of “information overload”.

The contents are listed in a sensible order dealing with Resuscitation and Trauma first—followed by Cardiovascular, Respiratory, Digestive systems, and so on. There are full chapters on Eye, Dental ENT, Obstetrics and Gynaecology and Psychiatric Emergencies as well as Crisis intervention. Ultrasound in emergency medicine is given a chapter of its own in keeping with the interest in emergency ultrasound in Australasia. Various legal and administrative issues are dealt with providing information on an area often neglected in emergency medicine training. The management of environmental hazards are dealt with and given considerable attention.

The result is a pleasing paperback book full of up to date information that will be as useful to the specialist as it is to the trainee.

PETER FREEMAN
Auckland, New Zealand

Neurology is not generally perceived as one of the more glamorous medical specialties. This textbook has an upbeat approach. In the preface, the author borrows the now ubiquitous “golden hour” concept for acute neurology.

The text is said to be “brief to facilitate reading” and “is intended to reflect the train of thought and action in the emergency department”. Compared with the average neurological textbook it may be brief but it would not be recognised as such by most emergency physicians.

The book is divided into two sections. The first covers conditions affecting the neuroaxis and the second, neurological disorders attributable to specific causes. Detailed descriptions of a number of neurological conditions and their aetiology are provided. The usual neurological emergencies are included, for example, status epilepticus and aneurysmal subarachnoid haemorrhage. In addition rather less obvious emergencies such as acute obstructive hydrocephalus and acute white matter disease are also discussed. The chapter on altered arousal and coma contains an exhaustive list of the major causes of coma, some of these conditions are unlikely to present to the emergency department. However, the detail contained within the sections on examination of the patient in coma and the assessment of patients with acute unexplained masses re-
minded me of a number of long forgotten clinical signs. In many chapters there is a brief but detailed and informative review of anatomy and pathophysiology. Many of the investigations, for example, EEG, SPECT suggested in other chapters might be problematic to arrange in the average emergency department. “I want a SPECT stat”.

In parts the clinical practice described does not follow current UK practice (or even standard clinical practice of 10 years ago). For example, it is implied that the administration of antibiotics in bacterial meningitis be delayed until CT/MRI and lumbar puncture have been performed.

The book is unlikely to be used “acutely” on a daily or weekly basis. I suspect this book is akin to an interview suit, something to be dragged out on rare, special and stressful occasions. It will prove a useful reference book for those reviewing cases, those on a neuroscience secondment or doctors preparing for examination. What were those five causes of upgoing plantars and absent ankle jerks again?

SUSAN M ROBINSON
Accident and Emergency Department, Addenbrooke’s Hospital, Cambridge

The late great Ernie Wise was the perfect example of an author so dazzled by the brilliance of the plays what he wrote that he was blind to the inherent flaws. Unfortunately, such delusions of literary grandeur are not unique and some authors seem to have difficulty in accepting that we are not all imbued with natural skills in the art of writing. Indeed, Richard Asher, regarded by many as the doyen of medical writing, prepared draft after draft of his articles before allowing them to proceed.

In this superb book by Tim Albert, there are fascinating and invaluable insights into the creative process. The style is hugely accessible and entertaining. One of the major highlights is official permission at last to boldly split infinitives!

The author writes with over 10 years experience of working with doctors to sort out a wide range of writing problems, noting that doctors have usually had no formal training in writing since they were 16, and are expected to publish in high status journals if they are to advance in their careers.

There are a large number of topics arranged alphabetically from abbreviations (for some reason Aardvark is overlooked) to zzzz. The book is intended to be dipped into for morsels as required including top tips on preparing your CV, writing style, scientific papers, references, press releases, posters, newsletters and even obituaries. The previously mysterious world of writing terminology is unveiled with explanations of IMRAD, salami publication, peer review and the impact factor. The sections on how to deal with rejection and editor (dealing successfully with) were particularly useful for this author.

For anyone considering dipping a toe into the literary pool or those who are already out of their depth, this book is an absolutely invaluable aid.

JOHN HEYWORTH
Consultant, Emergency Department, Southampton General Hospital

In this second edition David Currie, a Scottie neurosurgeon, has been joined by two anaesthetists to provide a handy guide for the management of patients with head injuries aimed instead of < is high in the emergency room and ward setting. A welcome addition is the excellent chapter on the disturbed patient, which will be appreciated by nurses on wards that are often under staffed. Advice with which most A&E specialists would agree includes “observation should ideally be undertaken on a neurosurgery ward”.

There could be more detail on the practical issues of how the “frontline” staff can safely and efficiently sort out difficult patients with complex problems. When they arrive in A&E, patients rarely have “isolated head injury” stamped on their foreheads yet I believe this is the way neurosurgeons would like to receive them. The management of potential alcohol withdrawal deserves more than a mention. I am concerned about the use of a contraction of the 15 point GCS score to a total of 14—this could create confusion in clinical discussions if the score is used without clarifying the denominator, for example, GCS < 8 instead of < 9 is high in the emergency room and ward setting. The importance of describing the levels of the three responses and avoiding numbers should be emphasised.

It is good that ATLS principles are espoused and there is an expanded chapter on cervical spine injuries but the inappropriate term “traction” is still used rather than “in line immobilisation”. Scalp “lacerations” should be differentiated from “incised wounds”—an important clue to the likely mechanism. Some typographical errors and mislabelling are retained and, in my copy, the clarity of some photographs has deteriorated compared with first edition.

Possibly because of the timing of this edition, it excludes the guidelines for the initial management of head injuries by the Society of British Neurological Surgeons (1998), which, for example, recommend computed tomography within four hours for GCS 15 patients with skull fracture.

This book about a common A&E presentation is written mainly for A&E staff by non-A&E specialists. To justify its title there needs to be a greater focus on what really happens in the emergency room everyday and an up to date view of what we should be doing in the future.

IAN SWANN
Consultant in Accident and Emergency Medicine, Glasgow Royal Infirmary

ABSTRACT

The following was omitted from the abstracts published in the November 2000 issue of the journal for the Millennium Scientific Meeting hosted by the Faculty of Accident and Emergency Medicine.

Minor injury services—the present state

M W COOK, J HIGGINS, P BRIDGE
Emergency Medicine Research Group, Centre for Primary Health Studies, University of Warwick, Coventry

Introduction—There are no studies describing the present systems of care in minor injury units. BAEM has recently issued a position statement but it is not known how many units adhere to this.

Methods—Postal questionnaire to all minor injury services in the UK.

Results—There was a 65% response rate. Units described themselves as minor injury services (32%), injury and illness services (24%). Eight per cent receive all local 999 ambulances but 24% receive none. The distance from the A&E department was under 10 miles for 9% of units. Only half are open 24 hours per day although most are open seven days a week. GP’s are the main provider (49%); with ENP the main provider in 27%. Only 15% had doctors permanently based in the unit and 50% had nurses permanently based in the department. Only 4% of nurses rotated with A&E. Over half had not have staff with ALS on duty at all times. They had high review rates.

Conclusions—Structure and staffing are highly variable. Most do not conform to BAEM guidelines. Optimal configuration is not known. More A&E input may be beneficial. Full report available at www.emerg-uk.com on reports page.

Funding—Department of Health A&E Modernisation Programme.
