Whiplash associated disorders: a review of the literature to guide patient information and advice

T McClune, A K Burton, G Waddell

Objectives: To review the literature and provide an evidence based framework for patient centred information and advice on whiplash associated disorders.

Methods: A systematic literature search was conducted, which included both clinical and non-clinical articles to encompass the wide range of patients’ informational needs. From the studies and previous reviews retrieved, 163 were selected for detailed review. The review process considered the quantity, consistency, and relevance of all selected articles. These were categorised under a grading system to reflect the quality of the evidence, and then linked to derived evidence statements.

Results: The main messages that emerged were: physical serious injury is rare; reassurance about good prognosis is important; over-medicalisation is detrimental; recovery is improved by early return to normal pre-accident activities, self exercise, and manual therapy; positive attitudes and beliefs are helpful in regaining activity levels; collars, rest, and negative attitudes and beliefs delay recovery and contribute to chronicity. These findings were synthesised into patient centred messages with the potential to reduce the risk of chronicity.

Conclusions: The scientific evidence on whiplash associated disorders is of variable quality, but sufficiently robust and consistent for the purpose of guiding patient information and advice. While the delivery of appropriate messages can be both oral and written, consistency is imperative, so an innovative patient educational booklet, The Whiplash Book, has been developed and published.
Grade IV (fracture or dislocation) and surgical interventions were excluded. Initially, abstracts of the retrieved articles were screened by one of the authors for their general content; full papers were obtained for those that appeared applicable. Acceptable studies and reviews were then selected as those that presented information relevant to the management and treatment of whiplash, together with selected articles covering epidemiology, mechanisms of injury, and social policy. Articles not pertinent to the development of patient information, or that did not add to the understanding of injury mechanisms or management in WAD, were excluded. In some areas (notably patient education) the whiplash literature was seriously lacking, so background evidence was taken from selected papers in other musculoskeletal conditions. In addition to the formal search, a few papers published in the last two months of 2001, which were especially relevant to the objectives of the review, were included.

A full systematic review methodology in such a multidisciplinary field would be impracticable and inappropriate, so an alternative strategy had to be adopted. This was based on a qualitative evaluation of the available scientific evidence in each relevant field for its appropriateness for developing patient information. Included articles were scrutinised and the pertinent information extracted; extensive discussion, reiterative drafting, and consensus between the three reviewers resulted in the synthesis of evidence statements reflecting the evidence currently available, while recognising the limitations of that evidence in many areas. Evidence statements were categorised under a number of headings: biomechanics, epidemiology, clinical, investigation, psychology, theoretical models, treatment, education, and social policy (though inevitably there was some overlap between these headings). The strength of the evidence for each statement was then rated qualitatively on its quantity, quality, and consistency by consensus between the three authors:

- **Consistent**: Generally consistent findings in multiple studies (albeit of variable scientific quality).
- **Balance**: Balance of available evidence (including existing reviews).
- **Limited**: Limited or weak scientific evidence.

Thus, the literature review may best be summarised as systematic searching of the published scientific literature with a qualitative evaluation of the quantity, consistency, and relevance of the evidence as the basis for patient information and advice on WAD.

**RESULTS**

One hundred and sixty three papers were included in the review and examined in detail. Table 1 lists the evidence statements (with identifying letters) together with a rating of the evidence and links to the references.

The QTF found very little scientifically admissible data. Having examined all material published since 1994, we feel this is, by and large, still the case. Published studies frequently have methodological shortcomings such as low sample sizes, differing inclusion/exclusion criteria and differing outcome measures, although there were some notable exceptions. In view of the limitations of the scientific evidence we believe, in common with the QTF, that a “best evidence synthesis” is appropriate, and our findings show this can provide a useful overview that highlights areas where there is a reasonable degree of consistency.

**Biomechanics**

Biomechanical considerations give some insight into the likelihood of injury, the tissues involved, and the severity of injury. Consistent evidence from both in vitro and in vivo studies suggest that a whiplash type injury can result in tissue injury to various spinal structures; potentially affecting the intervertebral discs, zygapophysial joints, ligaments and muscles (see table 1: B1, B6, B7). The majority of whiplash injuries probably involve predominantly muscles and ligaments, resulting from direct stretching or neuromuscular reflex contractions (B2). Many road traffic accidents involve quite low acceleration perturbations, which are similar to other daily living/sport activities (B5). Consistent findings indicate that relatively low velocity changes can be associated with tissue damage, with the threshold suggested to be 10–15 km/h (B3); yet claims may be made for symptoms resulting from accidents with even lower velocity changes (B4). The direction of impact has an influence: for similar vehicle masses, a higher velocity change is required for tissue damage in a front impact or side impact compared with a rear impact, and a poorer prognosis is likely if the neck is rotated or side bent at the time of impact (B9). There is considerable interest in the influence of head restraints on the effects of injury: theoretically head restraints can reduce the incidence and severity of WAD; there is some consensus that the optimum position for a head restraint is close to and level with the head (B8).

**Epidemiology**

Data from different countries suggest that recovery rates from WAD differ, probably depending on social and cultural influences. In cultures of low therapeutic involvement and no litigation, symptoms are short lived with little or no link to chronicity (E6). While there has been criticism of the methodology of these studies, the published data are largely consistent. The prevalence of chronic neck pain after a whiplash injury is very similar to the prevalence of chronic neck pain in the general population (E1), making it difficult to determine if persisting symptoms are directly related to the injury or are simply a reflection of the high prevalence of non-specific neck symptoms in the population at large. From an epidemiological perspective, it is clear that those with continuing symptoms three months after the accident are likely to remain symptomatic for at least two years, possibly much longer (E2). As with other chronic musculoskeletal disorders, people with chronic WAD typically have a high level of multiple complaints (E3). A poorer prognosis has been suggested for certain factors, although the quality of the evidence and the effect size varies: female sex, older age, a high level of symptom severity at onset, pre-traumatic headache, a greater number of symptoms, and pre-existing degenerative changes on radiograph (E4). There is limited evidence on an increased level of symptoms after a second whiplash injury (E5).

**Clinical history and examination**

There is conflicting evidence on the value of physical examination in the clinical setting. While a clinical history and physical examination are important to establish the WAD grade (and to identify or exclude more serious injuries), the findings do not pinpoint sources of pain and are not closely related to prognosis (C1). The most common presenting symptoms are, in descending frequency: neck pain, neck stiffness, headache, low back pain, shoulder pain, and visual disturbance/dizziness (C4), while generalised hyper-excitability and central nervous system sensitisation has been described in a number of studies of patients with chronic WAD (C6). There is persuasive evidence that the clinical outcome at two years can be predicted at three months. It seems that patients who are symptomatic after three months will remain so after two years or more, although their symptoms will fluctuate during this period. The two year outcome can be predicted with an 82% success rate using a combination of psychological score and neck stiffness assessed at three months (C2). There is consistent evidence that non-collision factors are important in the development of chronic symptoms (including fibromyalgia), emphasising the role of
psychological and cultural factors (C3), and there is considerable individual variability in terms of response to the accident itself and any resultant symptoms (C5).

**Investigations**

According to QTF and BCWI, imaging is unnecessary in Grade 0-I, but should be performed for Grade II-III to exclude possible fracture or dislocation; though it was accepted that incidental findings unrelated to the injury can be highlighted unnecessarily. More recently, it has been suggested that the extent of radiography could safely be reduced substantially through simple clinical screening, thus limiting unnecessary investigation and consequent costs (In4). The present review suggests that an MRI scan is generally not necessary for Grades 0-II, and probably only helpful for Grade III if surgery is being considered (In1). MRI scans will reveal a high number of abnormalities, particularly age related changes, in symptom free individuals as well as patients (In2). Conversely, while a high level of abnormalities on MRI has been associated with a poorer prognosis in WAD patients, these abnormalities are most commonly degenerative changes not specifically related to the neck injury (In3).

**Psychology**

A whiplash injury can certainly trigger emotional and cognitive changes, including travel anxiety, post-traumatic stress disorder, depression, fear of movement, catastrophising, sleep disturbance, and lower levels of concentration (P1, P6). These psychological changes, resulting either from the accident or from the subsequent symptoms and disability, develop secondarily during the first three months after the accident, and do not imply that the pain is psychogenic (P2). When present, psychological factors have a significant detrimental effect on outcomes (including return to work), and recovery tends to parallel psychological improvement (P6, P7). Chronic WAD patients may exhibit inaccurate expectations and amplification of symptoms; they may attribute their entire symptom pattern directly to the road accident, thus contributing to a perpetuation of their problem (P3). Specific coping strategies (active problem solving and perceived confidence in ability to complete daily activities) may be helpful (P5).

**Models**

Numerous models have been proposed to explain WAD. It is generally accepted that the biopsychosocial model can explain many clinical and epidemiological findings in WAD (M1). Accepting an injury event does occur, there is clear evidence for a biological component in the acute presentation (M2). The evidence suggests, however, that the development of chronic symptoms is influenced more by psychological, social, or cultural factors (M3, E6). More controversially, it has been argued that evidence for the construct validity of a causal link between the trauma mechanism and chronic symptoms is sparse, and that whiplash can be conceptualised as being a risk factor for cervical symptoms rather than representing a discrete disease entity (M4).

**Treatment**

It has been shown consistently in randomised controlled trials that an early active management strategy is most effective for WAD patients (Grade I to III) (T2). This includes return to pre-accident activities as soon as possible (T1), analgesic medication to control symptoms and permit increased activity levels (T4), and prescription of neck specific exercises (T7). Manual therapy (T6), and psychosocial interventions (including cognitive behavioural therapy) may be helpful, particularly for achieving early activation (T5). Collars, rest, and passive physical modalities are generally unhelpful (T3, T8). While the use of a soft collar can ease acute symptoms there may be a risk of promoting illness behaviour, especially if used beyond 72 hours (T3). Ill directed and blanket treatment approaches seem likely to contribute to chronic symptoms (T9). Radiofrequency neurotomy can be considered for chronic symptoms (T10), but the relation between those symptoms and the injury may be uncertain (E1). There is limited evidence for the effectiveness of antidepressants in WAD (T11).

**Education**

There is general consensus that appropriate information and advice is important (Ed1); while there is little information on educational interventions specifically for WAD, there is persuasive evidence from other musculoskeletal literature. It is known that patients want and seek information on health issues (Ed2), and it is important that that information is easy to read, understandable, acceptable, authoritative, believable, and contains practical advice (Ed3). Patients appreciate and retain knowledge from health educational booklets (Ed4); evidenced based patient education (particularly for low back pain) has been shown to have some effect in creating positive shifts in beliefs, improving clinical outcomes, and reducing work loss (Ed4). To counter negative cultural influences on recovery and inconsistent advice given by healthcare professionals, early delivery of evidenced based information may be optimal for assisting the return to normal activities (Ed4).

**Social policy**

The literature showing national and geographical differences in symptom reporting and recovery rates for WAD imply that social factors exert an influence on symptomatology and disability (S1). There is limited evidence to suggest that cultural over-medicalisation may contribute to illness behaviour (S2). Other potential social effects will be outside the control of health care, and involve legal and statutory bodies. Whiplash injuries represent a substantial cost to society, much of which is accounted for by cases lasting over six months (S3); there is therefore a logical basis for early intervention strategies to reduce the significant individual and societal costs.

**DISCUSSION**

The important sources of guidance for the management of whiplash (QTF, BCWI) recommend that patients be given reassuring information and advice. The results of this review support that position, and provide a stronger evidence base that active management strategies should have a beneficial influence on outcomes (table 1).

The limitations of this review, its methodology, and the available evidence must be recognised. The literature was searched systematically but, as already emphasised, a proper systematic review methodology was impractical and inappropriate. This was mainly because of the aims and scope of the review, and the range of material included, which was far beyond the randomised controlled trials for which the standard systematic review methodology was designed. Adherence to strict methodological criteria would have excluded much valuable information important to patients and their clinical management. The scope of the review and the criteria for rating the evidence were set to maximise the information available in an area not characterised by high quality studies. In common with QTF, a “best evidence synthesis” seemed the most profitable method for extracting appropriate patient centred messages. In the event, while some areas of the whiplash literature are clearly lacking good scientific evidence, there is a high level of consistency and consensus in many of the areas most pertinent to patient education. There remains, though, a clear need for randomised controlled trials to inform on specific treatment/management protocols, and their optimal timings.

### Synthesis of patient centred messages

The following core set of evidence based messages represents the information and advice that can be given to patients presenting with a WAD. These messages should be conveyed as soon after injury as is reasonably practical. As consistency of information is of fundamental importance, they are presented as a simple list of concepts that all clinicians treating or advising the patient should deliver. Accepting that discussion time with the patient is limited in accident and emergency departments and primary care environments, it is likely to be helpful if the patient can access the same information and advice in written form. To this end, the messages concerned have been incorporated into a booklet that, after peer review and patient evaluation trials, has been published as The Whiplash Book.

After clinical assessment to rule out WAD Grade IV, tackle the following issues, emphasising that they are based on the latest medical research:

- Accept there has been an injury to the neck, but emphasise its benign nature: *There has been no serious damage. After a whiplash injury the neck is simply not moving and working properly. The muscles and joints have been affected but they have a natural ability to repair and restore, which is helped by activity.*
- Emphasise the favourable prognosis: *It should improve rapidly with an active approach; there is no reason why long term disability should ensue. Although symptoms may persist for a while, the acute pain will improve within a few days or weeks, certainly enough to get on with life.*
- Recognise other symptoms: *Headache, arm pain, jaw pain, and dizziness are common and not a reason for concern.*
- Pain control: *Use simple analgesia; it’s an aid to increasing early activity. Try to find a way to relax and don’t worry.*
- Prolonged inactivity is unhelpful: *Avoiding daily activities slows recovery. Some activities may involve some pain, but hurt is not the same as harm.*
- Staying as active as possible is important: *Keep moving, don’t stay in one position too long, move about before you stiffen up, and don’t completely avoid things. Most daily activities and early return to work are helpful.*
- Exercises are helpful: *Simple neck and shoulder exercises are safe and effective—stretching, strengthening and coordination exercises should be done regularly each day; initial soreness is not a reason for concern.*
- Psychological factors (notably distress and fear) are risk factors for chronicity: *Don’t worry and don’t be frightened of movement or pain—activity and a positive approach are the keys to avoiding long term problems. Don’t be an avoider.*

In summary, the scientific evidence published on WAD since 1994 has increased in scope and quality. In particular, the concept of an early active management approach has been given added strength. Yet the precise mechanism of injury in the majority of patients is still open to speculation and even under active management a proportion of patients will progress to chronicity and remain a clinical challenge. The use of positive reassurance and evidence based advice, given consistently in both oral and written form, is an attractive and inexpensive intervention. Whether it will improve outcomes remains to be tested through randomised clinical trials.

### ACKNOWLEDGEMENTS

This review was funded by *The Association of British Insurers.*
