Simultaneous traumatic rupture of the quadriceps tendons

T. B. YOUNG

Accident and Emergency/Orthopaedics Department, Tameside General Hospital, Ashton-under-Lyne, England

SUMMARY

A case is reported of simultaneous traumatic rupture of the quadriceps tendons diagnosed in the accident and emergency department within 2 hours of injury. This is an extremely rare injury and diagnosis is often missed. Possible mechanism of the injury, predisposing factors, guidelines for diagnosis and results of surgical treatment are discussed, and the literature is reviewed.

INTRODUCTION

Rupture of the quadriceps tendons is uncommon. It may occur spontaneously or secondary to trauma. Bilateral rupture may happen simultaneously or the interval between each ruptured side may vary from a few minutes (Hinkamp & Pellicore, 1957; James, 1938) to 6 years (Graney, 1943).

Simultaneous rupture is a rare event whether it occurs after trauma or spontaneously (Levy et al., 1971; Norris & Levack, 1977; MacEachern & Plewes, 1984).

All but two of the previously reported bilateral cases were male and almost all aged 45 years and older.

CASE REPORT

H J, a 12-stone, 57-year-old male patient tripped on 16 October 1982, while descending a short staircase. In attempting to regain his balance, he contracted his quadriceps; his legs gave way and he hit his knees on the floor. He could not stand, and presented to the
accident and emergency department 2 hours later complaining of inability to straighten his knee. Pain was not a prominent feature.

On examination, there was a palpable suprapatellar gap bilaterally, and both knee joints showed evidence of an effusion. A presumptive diagnosis was made of rupture of the quadriceps tendon. X-rays were taken which showed osteoarthritic changes and low patellar position. There was new bone formation at the attachment of the quadriceps to the patellae on both sides, and interruption of continuity of the quadriceps tendon (Fig. 1).

There was no evidence of associated illness and he was not on any regular medication. Haematological and biochemical investigations were normal.

Bilateral complete rupture of the quadriceps tendon, 3 cm above the patella and extending into the quadriceps expansion, was confirmed at operation. A standard surgical repair was performed and the patient made a good post-operative recovery.

Eleven months after the operation he had full extension and flexion in both knees. There was no quadriceps weakness or reported restriction of his activities.

DISCUSSION

Traumatic rupture is caused by a violent contraction of the quadriceps against the flexed knee in an attempt to avoid a fall, or by hyperflexion of the knee (MacDonald, 1966; Preston, 1972). Spontaneous rupture occurs during ordinary daily activities, such
as walking (Wetzler & Merkow, 1950; Levy et al., 1971) or stepping from a car (Preston & Adicoff, 1962).

The pre-disposing factors in this case were similar to those of previously reported traumatic cases. The degenerative changes in the tendon were reflected by age, osteoarthritic knee changes and suprapatellar calcification. Pain may not be a prominent feature (Steiner & Palmer, 1949; Dalal & Whittam, 1966).

The important physical signs are knee effusion, palpable suprapatellar gap and the inability to extend the knee in the presence of contracting quadriceps.

X-ray will exclude fracture of the patella and more importantly it will show a low patellar position (Levy et al., 1971; Preston, 1972; Preston & Adicoff, 1962).

The patient reported here had complete functional recovery following early diagnosis and surgical repair; however, due to the rarity of the condition, delayed diagnosis is not uncommon (MacEachern & Plewes, 1984). Late surgical repair (MacDonald, 1966, 5 months; Preston & Adicoff, 1962, 8 months; Preston, 1972, 10 months) is usually associated with some extension lag, and is inferior to early repair.

ACKNOWLEDGEMENT

My thanks are due to Mr B. Goswami, Consultant Orthopaedic Surgeon, for his permission to report this case.
