Abstract

A short cut review was carried out to establish whether the seldinger “over the wire” technique is better than other techniques of pneumothorax drainage. Altogether 28 papers were found using the reported search, of which three presented the best evidence to answer the clinical question. The author, date and country of publication, patient group studied, study type, relevant outcomes, results, and study weaknesses of these best papers are tabulated. A clinical bottom line is stated.

Clinical scenario

A 30 year old man presents to the emergency department after a road traffic accident. On initial assessment you identify a haemothorax/pneumothorax on the left side of his chest; there are no signs of tension. You elect to place a chest drain and discover that you have a seldinger “over the wire” technique chest drain in front of you. You wonder whether this method of placement is better than any other at achieving successful management of the injury without complication.

Three part question

In [a patient requiring a chest drain after trauma] is [a seldinger “over the wire” technique better than other methods or chest drain placement] at [achieving pneumothorax resolution without complication]?

Search strategy

Medline 1966–12/02 using the OVID interface. [(exp chest tubes OR exp thoracostomy OR “chest drain$”.mp) AND (“seldinger”.mp OR “needle wire dilator”.mp OR “over wire”.mp OR “small bore”.mp OR pigtail.mp OR “pig tail”.mp)] LIMIT to human AND English.

Search outcome

Altogether 28 papers were found by the Medline search. No papers were directly relevant but three papers had some relevance to our clinical question. These are listed in table 1.

Comment(s)

There is no comparative work looking at the use of a seldinger technique for placement of chest drains in adult trauma patients. Of the papers that were found uncontrolled series reports document their comparatively safe use in adults and children in well controlled elective and intensive care settings. Complications such as recurrence of the pneumothorax, kinking of the drain do still occur as is seen in the open technique, but insertion complications or difficulties seem to be rare.
Antacids and diagnosis in patients with atypical chest pain

Report by Stewart Teece, Clinical Research Fellow

Checked by Ian Crawford, Clinical Research Fellow

Abstract

A short cut review was carried out to establish whether antacids can be used as a diagnostic test in atypical chest pain. Altogether 374 papers were found using the reported search, of which two presented the best evidence to answer the clinical question. The author, date and country of publication, patient group studied, study type, relevant outcomes, results, and study weaknesses of these best papers are tabulated. A clinical bottom line is stated.

Clinical scenario

A 57 year old man presents with a one hour history of central chest pain the character of which he cannot describe. There is no radiation but there is mild sweating and subjective shortness of breath. He has a history of smoking, hypertension, angina, and a hiatus hernia; the pain came on after a curry. He has a normal ECG on admission and an unremarkable examination. You cannot decide whether this is cardiac or oesophageal in origin and wonder whether a single dose of antacid might relieve his pain and therefore clarify the diagnosis.

Three part question

In [a patient with chest pain of uncertain aetiology] is [the use of antacids/alginites] useful for [differentiating between cardiac and gastro-oesophageal causes]?

Search outcome

Altogether 374 papers were found only two of which directly addressed the three part question (table 2).

Comment(s)

Both studies are small, however in the Henderson paper if the 95% confidence intervals are calculated (81.5% to 100% typical, 9% to 30.2% atypical) there is a distinct difference between the two groups despite all the patients having normal ETTs and angiography. A further paper by Davies et al has shown that the instillation of acid into the stomach decreases the angina threshold on exercise testing. The above tests would suggest that reflux affects angina and vice versa. The vagus nerve has been suggested as the common link between the two.

> CLINICAL BOTTOM LINE

Antacids are useful in the relief of pain that is clearly oesophageal in origin but the effect is insufficiently specific to be of value in aiding diagnosis.

Need for cervical spine imaging for alert children after trauma

Report by Andreas Kontos, Savvas Omorphos, Medical students
Checked by Joel Desmond, RCS Research Fellow

Abstract
A short cut review was carried out to establish whether clinical examination can be used to exclude cervical spine injury in alert children. Altogether 298 papers were found using the reported search, of which three presented the best evidence to answer the clinical question. The author, date and country of publication, patient group studied, study type, relevant outcomes, results, and study weaknesses of these best papers are tabulated. A clinical bottom line is stated.

Clinical scenario
An 11 year old boy is brought to the emergency department by paramedics after falling off his bicycle. They have immobilised his cervical spine with a hard collar. He has no visible external injury, is fully alert and cooperative and does not complain of any neck pain. You are aware of the “trend” for radiographic cervical spine imaging in virtually all blunt trauma patients, as unrecognised cervical spine injury can lead to disastrous neurological sequelae. However, you wonder whether imaging in this case is really necessary.

Three part question
In [alert children with suspected cervical trauma] is [clinical examination without cervical radiography] adequate to [exclude significant cervical injury]?

Search strategy
Medline 1966–12:02 using the OVID interface. [(exp spinal cord injuries) OR (cervical spine injur$mp)] AND [(exp x-rays) OR (x-rays.mp) OR (radiograph$mp)] AND [Best-BETS Paediatric filter] LIMIT to human AND English.

Search outcome
Altogether 298 papers were identified of which two were relevant. In addition NICE are undergoing a systematic review of head and cervical spine injury, and checking their search results, we found one additional paper that has not yet been indexed by Medline. These three papers are shown in table 3.

Comment(s)
Although the issue of radiographic assessment of children with suspected cervical injury has been addressed in several studies, there is still insufficient evidence to support diagnostic standards, as the incidence of cervical injuries among paediatric samples is low. To date, the Nexus criteria (absence of: (1) midline cervical tenderness, (2) altered alertness, (3) intoxication, (4) neurological deficit, and (5) painful distracting injury) provide the most reliable instrument for assessing the need for cervical spine radiography in paediatric blunt trauma victims. However, in doubtful individual cases, decision should be at the clinician’s discretion, as these criteria may not be 100% sensitive, because of the wide confidence interval around these findings.

> CLINICAL BOTTOM LINE
Cervical spine radiography is not necessary in paediatric blunt trauma victims over the age of 9 who are fully alert, conversant, show no signs of intoxication, have no neurological deficit, no midline cervical tenderness, and no painful distracting injury.

Cervical spine imaging in children under 9 after trauma

Report by Savvas Omorphos, Andreas Kontos, Medical students
Checked by Joel Desmond, RCS Research Fellow

Abstract
A short cut review was carried out to establish whether the odontoid peg view is useful to radiologically exclude cervical spine injury in children under 9 years of age. Altogether 156 papers were found using the reported search, of which two presented the best evidence to answer the clinical question. In addition recent guidelines are noted. The author, date and country of publication, patient group studied, study type, relevant outcomes, results, and study weaknesses of these best papers are tabulated. A clinical bottom line is stated.

Clinical scenario
You have just read a recent important publication by the American Association of Neurological Surgeons and the Congress of Neurological Surgeons who recommend that in the under 9 age group, children requiring radiological assessment of their cervical spine need only undergo an AP or lateral cervical spine view. It is your current practice to perform three
view radiography but you realise that getting the odontoid peg view can be very difficult in non-compliant children. You wonder on what evidence this specific guideline was based.

Three part question
In [children under 9 years old with suspected cervical spine injury] is [the odontoid peg view needed in addition to lateral and antero-posterior views] to [radiologically clear the cervical spine]?

Search strategy
Medline 1966–12/02 using the OVID interface. [((exp Spinal Cord Injuries$) OR (spinal cord injur$.mp) OR (cervical spine injur$.mp) OR (spinal fractur$.mp) OR (exp x-rays) OR (x-rays.mp) OR (radiograph$.mp)) AND ((exp odontoid process) OR (odontoid.mp)) AND [BestBETs Paediatric filter] LIMIT to Human AND English.

Search outcome
Altogether 156 papers were identified of which two were relevant. The reference list of the guidelines were also searched but these were the only two papers of direct relevance. The two papers and the guidelines are summarised in table 4.

Comment(s)
The comprehensive review of the literature by the American Association of Neurological surgeons in 2002 come to the conclusion that odontoid peg views in the under 9 age group are unnecessary. However, Swischuk et al in their survey of 432 paediatric radiologists report that they have identified 46 fractures, seen on the odontoid peg view that could not been seen on the lateral view. The American Association have set the current best evidence guidelines in this area but it should be remembered that they warn that these do not represent diagnostic standards and caution should be used in their application.

- CLINICAL BOTTOM LINE
Guidelines on cessation of the odontoid peg views in the under 9 age group should be viewed with great caution.

Conservative management of asymptomatic cocaine body packers

Report by Debasis Das, House Officer in Surgery
Checked by Baha Ali, Senior Clinical Fellow in Emergency Medicine

Abstract
A short cut review was carried out to establish whether asymptomatic cocaine body packers can be managed conservatively. Altogether 171 papers were found using the reported search, of which four presented the best evidence to answer the clinical question. <td>Search of Medline (1966–2001), Systematic review in the following subject headings: “spinal injuries” and “child” were reviewed with “cervical vertebrae,” “spinal injuries” and “child.” Altogether, 58 relevant articles were identified</td>
<td>Guidelines for the management of acute cervical spine and spinal cord injuries</td>
<td>Insufficient evidence to support diagnostic standards however the following are recommended: In children &lt;9 years of age who have experienced trauma and are non-conversant, or have neurological deficit, an altered mental status, neck pain, or a painful distracting injury, are intoxicated, or have unexplained hypotension it is recommended that anteroposterior and lateral cervical spine radiographs be obtained.</td>
<td>Search strategy is not fully described in this paper. Note authors came to their recommendations largely on the two other studies summarised above.</td>
<td></td>
</tr>
</tbody>
</table>

Outcomes, results and study weaknesses of these best papers are tabulated. A clinical bottom line is stated.

Clinical scenario
You are called to see a young adult male who is accompanied by two members of Her Majesty’s Customs and Excise. They tell you that he is under suspicion of trying to smuggle drugs into the country and that he may have done this by ingesting packets of cocaine. Physical examination is unremarkable, but abdominal radiography does reveal multiple, oval foreign bodies. Physical examination is unremarkable, but abdominal radiography does reveal multiple, oval foreign bodies. You wonder whether to simply leave the patient as he is and observe him for signs of obstruction and/or pending cocaine toxicity, intervene conservatively and do the latter as well, or do something more aggressive to remove the packages from the patient’s intestines.

Three part question
In [asymptomatic patients who have swallowed packets of cocaine in order to smuggle them across borders] is [conservative management] effective at [preventing the morbidity and mortality associated with body packing]?

Search strategy

Search outcome
Altogether 171 papers found of which 111 were irrelevant and a further 57 papers were unsuitable for inclusion due to either having insufficient patient numbers to be useful (usually single/double case reports—range: 1–7 patients, n=36 papers, including five letters/editorials), or for being irrelevant to the other core issue of how to actually manage cocaine packet ingestion (n=19 papers—usually on only investigating body packing). In addition one more relevant paper, not yet indexed on Medline was found The four papers are shown in table 5.

Comment(s)
It has generally become accepted that cocaine body packers who show signs of cocaine toxicity or gastrointestinal obstruction need emergency surgery. Additionally, when packets show signs of in vivo degradation (passing pieces of sloughed packet wrappings or actual packets with deteriorated packaging) emergency surgery may also be warranted. The general management plan in asymptomatic cocaine body packers would seem to be conservative management consisting of mild laxatives and light solid or clear liquid diet with close monitoring and intravenous access maintenance throughout. Treatment usually ceases with the passage of at
least two packet free stools, with or without supporting radiographic data (abdominal radiograph/ KUB), and only McCarron and Wood suggest using suppositories to obtain non-obstructing, intra-rectal packets.

That said, details such as management environment (intensive care/high dependency unit, emergency department, or general ward?) still remain unclear, and because none of the series mentioned above are prospective, randomised control trials, the validity of their results can also be called into question.

> CLINICAL BOTTOM LINE

The best evidence available suggests that asymptomatic cocaine body packers can be managed conservatively until they have completely passed their packets. Close clinical observation in the meantime allows for the early detection of patients developing complications that may require emergency surgery.

### Acute myocardial infarction in cocaine induced chest pain presenting as an emergency

Report by Simon Carley, Specialist Registrar

Checked by Baha Ali, Senior Clinical Fellow

Abstract

A short cut review was carried out to establish the incidence of acute myocardial infarction in patients presenting as emergen-

cies with post-cocaine chest pain. Altogether 198 papers were found using the reported search, of which eight presented the best evidence to answer the clinical question. The author, date and country of publication, patient group studied, study type, relevant outcomes, results, and study weaknesses of these best papers are tabulated. A clinical bottom line is stated.

**Clinical scenario**

A 32 year old man presents to the emergency department with central chest pain suggestive of cardiac ischaemia. He has had pain for 50 minutes after nasal cocaine. He is an occasional cocaine user who has not had chest pain previously. He is previously well. His 12 lead ECG is normal and he is now pain free. You see him in the resuscitation room and prescribe oral aspirin 300 mg. He is cardiovascularly stable. You admit him and do a 12 hour troponin T, which is normal. The next day a colleague suggests that there was no need to admit as he was well, had a normal ECG, had few risk factors, and that as cocaine causes spasm rather than clots he could have gone home. You wonder whether this is good advice.

**Three part question**

In [patients presenting with cocaine associated chest pain] what [is the incidence] of [acute myocardial infarction]?

**Search strategy**

**Search outcome**

No relevant papers found on Cochrane library. Altogether 198 papers were found on Medline of which eight were relevant to the three part question (see table 6).

**Comment(s)**

The incidence of acute myocardial infarction in cocaine associated chest pain is small but significant. The ECG seems to have
a higher false positive rate in these patients. A normal ECG reduces but does not exclude myocardial damage. Most acute myocardial infarction patients will present with ST elevation or an abnormal ECG. Many of the above papers exhibit selection bias as only admitted patients are used, this may account for some of the higher incidences recorded. They also enrol patients who have taken cocaine hours before symptomatology, this contradicts the known pharmacology of cocaine. Early presentation after cocaine use would normally be expected. It must be remembered that some of the reported incidence will be coincidental rather than causative. Those patients presenting with normal findings, and a normal ECG have a low but not absent acute myocardial infarction risk. They should have myocardial damage excluded.

**CLINICAL BOTTOM LINE**

Acute myocardial infarction should be excluded using cardiac markers in patients presenting to the emergency department with cocaine related chest pain.
