Treatment of lower limb haematomas in elderly patients is complex. These patients often have multiple medical problems such as respiratory problems, cardiac problems, and arthritis. They are often taking drugs including warfarin, corticosteroids, and aspirin. Conventionally, patients with pretibial haematoma are managed under general or regional anaesthesia for evacuation of the haematoma and skin grafting if required. While the patient on the ward, waiting for results of investigations and optimising the patients general condition for surgery, the skin over the haematoma may undergo vascular compromise leading to skin necrosis and subsequent infection. The time taken for these patients to be assessed as fit for general or regional anaesthesia and for their overall condition to be optimised can compound the problem with necrosis of the overlying skin, contamination, and infection. The time spent may delay evacuation of the haematoma to the point where total skin loss over the haematoma results, necessitating skin grafts to the traumatised area.

Postoperatively these patients are at risk of developing deep vein thrombosis, pulmonary embolism, and other cardiovascular complications because of immobilisation. We evacuate these pretibial haematoma as soon as possible after the injury, to reduce the risks of skin necrosis and secondary infection. The procedure can be done without the need for general anaesthesia and postoperative immobilisation.

A safe and simple technique is described in this paper, which is used in the accident and emergency department or on the wards under local anaesthesia.

**TECHNIQUE**

**Position and pain control**
The procedure is performed with the injured leg elevated. The anaesthesia can be infiltration of local anaesthetic, haematoma block using bupivacaine with adrenaline and hylase or entonox (depending upon the availability).

**Incision (fig 1A)**
If there is a laceration along with the haematoma, this laceration is used as a port for the sucker or a stab incision is made in the skin overlying the haematoma.

**Evacuation (fig 1B)**
The Yankauer suction cannula is attached to the wall suction. The haematoma is then evacuated by to and fro movement of the cannula in the haematoma, which breaks the clots and sucks it as in liposuction. The cavity is then irrigated with normal saline. The laceration or the incision is left open for free drainage or can be closed with adhesive tapes (figs 2 and 3). The leg is dressed with compression dressing (fig 4). The patient is mobilised after the procedure (fig 5).

**DISCUSSION**
This technique allows us to evacuate the haematoma as soon as possible without general anaesthesia in the accident and emergency department or on the wards. The early evacuation of the haematoma avoids pressure necrosis of the overlying skin.
skin and secondary infection. It also helps us to buy some time to investigate the patient for fitness for general anaesthesia if a skin graft is required. Hence we can convert an emergency operation into an urgent elective operation. The technique is versatile, as it requires few instruments, the local anaesthetic agent, Yankauer suction cannula, wall or portable suction and compression dressings, which are readily available in accident and emergency departments and in wards.

The Yankauer suction cannula is a very efficient suction cannula with blunt end, multiple fenestrations and is available in sterilised form in different lengths. Compression bandaging is important to prevent further collection of haematoma and it also facilitates firm contact between degloved skin and underlying soft tissue.

It is not necessary to immobilise the patient and in appropriate cases may not require hospitalisation and can be treated as outpatient basis for change of dressing and monitoring wound healing.
