Relationship between Trendelenburg tilt and internal jugular vein diameter

S Clenaghan, R E McLaughlin, C Martyn, S McGovern, J Bowra

Objective: To evaluate the relationship between Trendelenburg tilt and internal jugular vein (IJV) diameter, and to examine any cumulative effects of tilt on the IJV diameter.

Methods: Using a tilt table, healthy volunteers were randomised to Trendelenburg tilts of 10°, 15°, 20°, 25°, and 30°. Ultrasound was used to measure and record the lateral diameter of the right IJV at the level of the cricoid cartilage. Following each reading the table was returned to the supine position. Balanced randomisation was used to assess cumulative tilt effects.

Results: A total of 20 healthy volunteers were recruited (10 men, 10 women). Mean supine IJV diameter was 13.5 mm (95% CI 12.8 to 14.1) and was significantly greater at 10° (15.5 mm, 95% CI 14.9 to 16.1). There was no significant difference between 10° and greater angles of tilt. The effect of the previous angle of tilt did not prove to be statistically significant.

Conclusion: Increasing the degree of Trendelenburg tilt increases the lateral diameter of the IJV. Even a 10° tilt is effective. The cumulative effect of tilt (that is, the effect of the previous angle) is not significant. Ultrasound guided cannulation is ideal, but in its absence Trendelenburg tilt will increase IJV diameter and improve the chance of successful cannulation. While 25° achieved optimum distension, this may not be practical and may be detrimental (for example, risk of raised intracranial pressure).

METHOD

A statistical analysis before the study predicted that 20 subjects would be required for sufficient power, and compared favourably with other similar studies. The procedure was carried out by a single examiner (SC) using healthy volunteers selected at random. The subjects had no history of neck problems or previous IJV cannulation.

Each subject was placed supine on a tilt table, with an inbuilt clinometer that was raised and lowered on an electric motor. The level of the cricoid cartilage and the right IJV was identified using real time ultrasound (Medison 128 BW high frequency linear probe). Lateral IJV diameter was measured at this level over three respiratory cycles and the maximum diameter was recorded prior to tilt. The subject then was tilted to 10°, 15°, 20°, 25°, and 30° Trendelenburg. For each angle, subjects were kept in position for 30 seconds prior to further measurement of maximum IJV diameter (again over three respiratory cycles) and then returned to the supine position before being placed in the next angle. The actual order of angles was randomly allocated for each subject using a balanced randomisation table, so that we could analyse the effects of prior angle and cumulative tilt.

RESULTS

We recorded and printed ultrasound images of maximal IJV diameter for each subject at each angle. The results were collated and we calculated the mean IJV diameter for each angle studied.

A factorial analysis of variance (including terms for angle, subject, previous angle, and period) performed with SPSS version 11 showed that previous angle (p = 0.76) and period (p = 0.68) were not significant. This also allowed us to include the zero tilt results that were always performed in the first period. We compared angles in pairs using Newman–Keuls multiple range tests and we also described the relationship between diameter and tilt angle using polynomial trends.

DISCUSSION

In the ED, patients who require emergent central venous cannulation are those in need of rapid infusion of fluids or drugs, or monitoring of central venous pressure because of cardiovascular instability. Cannulation in such patients is often difficult (for example, due to intravascular depletion) and may have an increased risk of complications such as failed cannulation, arterial puncture, haematoma, and pneumothorax.

In this context, institutions such as NICE recommend ultrasound guidance for central vein cannulation in order to...

Abbreviations: ED, emergency department; IJV, internal jugular vein; NICE, National Institute for Clinical Excellence
reduce the rates of complication and improve the rate of cannulation success. In the absence of ultrasound guidance most clinicians would use Trendelenburg positioning, though this can be poorly tolerated and associated with increased complications (such as risk of raised intracranial pressure) in some patient populations.\textsuperscript{5-7}

Our study demonstrates that $10^\circ$ Trendelenburg significantly increases IJV diameter in healthy adults, although this did vary greatly between individuals, with an actual distension of between 1.2 mm and 7.0 mm. There was a non-significant trend to further increases with greater angles of tilt, maximal at $25^\circ$; however, this increase was relatively small, with a mean of 1.2 mm. Larger studies may demonstrate significant increases at angles of tilt greater than $10^\circ$, although our subjects reported discomfort with angles greater than $10^\circ$. Furthermore, most ED trolleys tilt only to $10^\circ$ to $15^\circ$. Hence, greater angles of tilt are not only impractical in unstable patients but may also be of little benefit.

Armstrong et al.,\textsuperscript{3} Verghese et al.,\textsuperscript{8} and others\textsuperscript{9-12} have demonstrated that various manoeuvres are effective in increasing IJV diameter in healthy adults. The Valsalva technique is particularly effective and a combination of techniques has been advocated. However, the Valsalva technique is often impractical in critically ill patients.

In the present study, the effect of respiratory cycle on IJV diameter was overcome by measuring maximal diameter over three respiratory cycles for each subject at each angle of tilt. Interobserver variability was eliminated because only one researcher carried out the measurements.

CONCLUSION

Increasing the degree of Trendelenburg tilt increases the lateral diameter of the IJV. Even a $10^\circ$ tilt is effective. The cumulative effect of tilt (that is, the stretching effect of the previous angle) is not significant. Ultrasound guided cannulation is ideal but in its absence Trendelenburg tilt will increase IJV diameter and may improve the chance of successful cannulation. While $25^\circ$ may achieve optimum distension, this is impractical and may be detrimental. There was no benefit in tilting the patient to a steeper angle prior to settling at a lesser angle to carry out the procedure. There did not appear to be any “stretching” of the IJV to allow greater distension at a lesser angle.

Trendelenburg tilt is used in IJV cannulation to optimise conditions for successful cannulation. Our results show that IJV distension shows marked inter-subject variability and that minimal increases in diameter may occur. Although this may be statistically significant, is it clinically significant? It is difficult to say. This study was not designed to assess the success of cannulation, but it highlights a significant problem with blind cannulation in that we do not know, in an individual patient, how the IJV will respond. What we can do is provide optimum conditions to facilitate cannulation.

We recommend that practitioners use $10^\circ$ of tilt when attempting central venous cannulation in the absence of real-time ultrasound. However this technique assumes normal anatomy and therefore real time ultrasound is preferable.

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|}
\hline
Trendelenburg & Mean IJV diameter & 95\% CI & Range \\
angle & (mm) & & \\
\hline
0 & 13.5 & 12.8 to 14.1 & 9.9–23.5 \\
10 & 15.5 & 14.9 to 16.1 & 11.2–25.7 \\
15 & 15.5 & 14.8 to 16.1 & 10.7–26.2 \\
20 & 16.4 & 15.7 to 16.1 & 10.9–28.2 \\
25 & 16.7 & 16.1 to 17.4 & 11.7–25.4 \\
30 & 16.7 & 16.1 to 17.4 & 10.9–26.5 \\
