Detection of hypertension in the emergency department

J Fleming, C Meredith, J Henry

Objectives: To assess whether an emergency department (ED) is a suitable location for the targeted screening of hypertension.

Methods: This was a prospective targeted screening study based at the ED of an inner city teaching hospital. Non-acute subjects over 18 years were recruited consecutively from the “minors” section of the ED and invited to participate. All subjects had their blood pressure measured twice. A verbal numerical pain score (PS) out of 10 using a visual analogue scale was obtained. Those with a mean systolic blood pressure >140 mmHg or a mean diastolic blood pressure >90 mmHg (WHO JNC stage 1 hypertension) were invited for a subsequent follow up measurement. The primary outcome measure was the proportion of subjects with hypertension at follow up. The secondary outcome measure was the correlation between a subject’s mid blood pressure (MBP) and their PS.

Results: In total, 765 subjects were tested, of whom 213 subjects were hypertensive at presentation (28.7%). After excluding those on anti-hypertensive medication (n = 43; 5.6%) and those who were non-UK residents (n = 44; 5.8%), 126 subjects were invited for follow up, of whom 51 subjects actually attended (40% attendance, 6.6% of study population). The MBP of those who re-attended was significantly lower than at presentation (p<0.001; 39 subjects (5% of the study population, 76.4% of those attending follow up) remained hypertensive. There was no correlation between a subject’s PS and their MBP (Pearson correlation coefficient = -0.02). A 10/10 PS was associated with an 8.4 mmHg rise in MBP compared to the mean MBP of subjects with PS 0–9 (p<0.1). Of those originally presenting with PS>5/10, 62% still had hypertension at follow up when the painful stimulus was significantly reduced (mean PS = 0.6).

Conclusion: The ED provides an opportunity for identifying those individuals with hypertension who may otherwise remain undiagnosed. Caution is advised when diagnosing hypertension in those individuals suffering from anxiety and/or acute severe pain on presentation.

Hypertension is a major risk factor for cardiovascular diseases,1 which are still the leading cause of death in Europe and North America.2 In the UK, approximately 40% of all strokes are attributable to systolic blood pressures ≥140 mmHg. In the general population, 37% of coronary heart disease in men and 27% in women is attributable to hypertension.3 In addition, a recent meta-analysis of individual participant data from separate prospective studies has confirmed that blood pressure is strongly related to vascular and overall mortality, without any evidence of a threshold down to at least 115/75 mmHg.4

A recent National Heart Forum report highlighted the "major social class, regional and ethnic differences in rates of heart disease and risk factors. For example, the declining rates of heart disease appear to be concentrated among non-manual social groups.5 In addition, the urban poor have little access to health care delivery sites other than an emergency department (ED), and regard it as their regular and frequently their only source of care. The identification of undiagnosed hypertension in the community would serve as a powerful tool in combating heart disease. The UK National Service Framework aims to reduce variations in morbidity and mortality and to improve the overall standard of care for cardiac patients.6 Each year, about 15 million people attend EDs throughout the UK.7 This represents approximately 25% of the population. Depending on the location of the department (rural or urban; inner city or suburban), a proportion of these individuals, ranging from approximately 10 to 25% are not registered with a general practitioner (GP). For these patients, opportunistic screening for numerous potentially life threatening conditions is not available. We set up a small study to find out whether targeted screening for hypertension was feasible in the ED, an environment in which a largely unselected and often disadvantaged population can be examined and screened for disease.

METHODS
Design and outcome measure
This was a prospective targeted screening study. The primary outcome measure was the proportion of subjects with sustained hypertension at follow up after measurement at their initial ED presentation. The systolic and diastolic data obtained for each subject were used to calculate their mid blood pressure (MBP). The MBP (half the systolic blood pressure (SBP) plus half the diastolic blood pressure (DBP)) has recently been shown to confer the highest degree of predictability for stroke and coronary heart disease risk.8 A mean of two MBP measurements on the first sitting was compared to the MBP from the last of three measurements taken at follow up. The mean of two MBP measurements at presentation was used because any future ED based hypertension screening programme would be unlikely to measure BP more than twice on presentation. The third reading was used at follow up as this was felt to be a better indicator of a subject’s resting BP and may have alleviated any haemodynamic effects caused by stress and anxiety.

Abbreviations: BHS, British Hypertension Society; DBP, diastolic blood pressure; ED, emergency department; GP, general practitioner; MBP, mid blood pressure; PS, pain score; SBP, systolic blood pressure
The secondary outcome measure was the correlation between a subject’s MBP and their pain score (PS).

Location and materials
Researcher shifts normally lasted for 3 hours, with each 24 hour period fully covered during the length of the study. The same researcher, a fourth year medical student competent in measuring blood pressure by auscultation, performed all the blood pressure measurements in order to reduce interobserver variability and terminal digit preference, and to and give consistency to any error of measurement. A single mercury sphygmomanometer was used for all measurements and was calibrated and tested according to British Hypertension Society (BHS) guidelines. This was used in preference to an automated device because few studies have assessed the validity of these devices and up to 24% have demonstrated clinically significant errors. Automated BP devices can overestimate BP in hypotensive patients, and manual measurement can be more reliable in a trauma situation.

Subjects
Subjects were selected consecutively during the shifts. Each potential subject was given a verbal explanation and written consent was obtained. All patients invited to participate in the study were in triage categories 3–5 (non-urgent). Patients aged <18 years were excluded from the study as were those with suspected right upper arm or right shoulder injuries.

Pain scores
A visual analogue pain score sheet was constructed using several languages to help pain assessment, with scores out of 10.

Measurement
The study adhered to strict BHS protocol. Manometer position and the position and height of each subject’s arm remained constant throughout. After a systolic palpatory estimation of systolic pressure was performed, auscultatory blood pressure was measured using a 26 × 12 cm cuff. A 40 × 12 cm cuff was used only when the cuff did not hold during inflation. The diastolic reading was noted at Korotkoff phase V, except in pregnant women, when Korotkoff phase IV was used. A rest period of 5 minutes was observed before the first measurement was performed. All measurements were made on the right arm in the seated position. A second reading was obtained 2 minutes after the first.

Follow up
Those subjects who either had a mean SBP >140 mmHg or a mean DBP >90 mmHg (that is, stage 1 hypertension and above) were invited for follow up. Although MBP is the best predictor of morbidity and mortality, for the purposes of actually identifying those with hypertension, the World Health Organization definition was used. A letter was delivered to each subject either by post or by hand at the GP’s abode. Those subjects that did not re-attend were reminded by telephone and invited back at a time convenient to them.

RESULTS
In total, 765 subjects were seen in total during the 6 week study, of whom 213 (27.8%) were hypertensive. After excluding those receiving antihypertensive treatment or with a history of the condition and those who lived abroad or who were temporarily in the UK, 126 (16.5%) subjects were invited for follow up, of whom 51 (40%) actually attended their appointments. The average time lag between presentation and follow up was 12.4 days (range 5 to 23). The number of hypertensive subjects at follow up was 39, (5% of the sample population), and all subjects attended the ED purely for the purposes of follow up. Fig 1 shows an overview of the results.

Follow up
Of the 51 subjects who attended the ED purely for the purposes of follow up over a 30 day period, 45 (88.2%) had blood pressure in the high to normal category or above at the third reading. The total number found to be stage 1 hypertensive or higher was 39 (76.5%), of whom 17 were not GP registered. Six subjects fell into the normal and optimal categories (11.8%). A paired t test was performed, comparing the mean MBP at presentation with the third MBP reading obtained at follow up of each of the 51 subjects who attended follow up. There was a significant difference in MBP at follow up compared with presentation (p < 0.001). As two subjects did not give their consent to us informing their GP and 17 subjects were not GP registered, 20 letters were sent to GPs informing them of our findings, and 17 letters went to the home addresses of those patients who were not GP registered.

Sex specific follow up
In total, 76% of men and 68% of women remained stage 1 hypertensive or above at follow up.

The effects of pain on blood pressure
Those subjects who presented with a 10/10 pain score had a mean MBP 8.4 mmHg higher than the mean for all other PS (p < 0.1) (fig 2). By comparing the 13 subjects who presented with severe pain (≥5/10) who were subsequently seen at follow up with pain ≤1/10, we could see the effects of severe pain on blood pressure (fig 3).

DISCUSSION
This study showed that 5% of ED attendees (triage category 3–5) had hypertension that was sustained at follow up. In an ED with 53,940 patients attending per year, this represents at total of at least 2697 patients annually. Although the mean MBP was significantly lower at follow up than at presentation, 39 subjects (76.4%) remained hypertensive. Of the 40% attending follow up, the results equate to a prevalence of previously undiagnosed hypertension, confirmed by follow
of follow-up rate could have been improved if a longer period had been allowed.

It is unclear whether those attending follow up were representative of the sample population with raised blood pressure on presentation. Those who attended their follow up appointment might have been more likely to want to change their health behaviour and make positive changes to their lifestyle to reduce their overall cardiovascular risk. Follow up contributions by these subjects may underestimate the prevalence of a condition such as hypertension. However, those who did not re-attend, despite phone calls encouraging them to do so, may be more likely to avoid such health promotion efforts. It is not known whether those subjects found to be hypertensive at follow up were commenced on successful treatment. Further study could follow subjects referred to primary care for assessment and treatment, allowing the usefulness of this case finding exercise to be evaluated.

In any scenario involving blood pressure measurement, the lability of the haemodynamic system poses challenges. It is hoped that the strict BP measurement protocol employed in this study alleviated the effects of “white coat” hypertension. SBP was particularly labile and we hoped that the third reading at follow up permitted a suitable regression of a subject’s MBP to the mean.

Of 13 hypertensive subjects presenting to the ED with pain rated >5/10, 62% remained hypertensive at follow up, even though the mean PS was then <1/10. The inherent subjectivity of the visual analogue scale cannot be overlooked. The effects of over the counter analgesics, pain produced only on
Detection of hypertension in the emergency department

WHAT IS ALREADY KNOWN ON THIS TOPIC

- Hypertension is a major risk factor for cardiovascular morbidity and mortality.
- The urban poor have little access to healthcare delivery sites other than an ED and regard it as their regular, and frequently their only, source of care.
- The government aims to reduce coronary heart disease and stroke mortality by at least 40% in people <75 years of age by the year 2010.
- Hypertension can be effectively controlled by lifestyle changes and pharmacological intervention.

WHAT THIS STUDY ADDS

- Detection of hypertension is feasible in the ED.
- 5% of ED attendees remained hypertensive at follow-up.
- The ED could enhance disease detection in this hard to reach population.
- Caution is advised when diagnosing hypertension in those ED patients with acutely painful presenting complaints.
- Hypertension in the ED patient population should not automatically be put down to a painful presenting complaint, and repeat measurement should be performed before discharge.

Hypertension is well known as a major risk factor for cardiovascular and cerebrovascular morbidity and mortality. However, in ethnic minority communities; 32.5% of hypertensive individuals still remain undiagnosed despite the increased emphasis on detection. The National Service Framework aims to reduce coronary heart disease and stroke mortality by at least 40% in people <75 years of age by the year 2010. The GP is often the person given the task of diagnosing hypertension in the community. This study by Fleming et al examines the feasibility of detecting hypertension in the ED, which is often used by those who never attend a GP. It found that 5% of ED patients had undiagnosed hypertension. This is another way of tackling the burden of cardiovascular illness.

Should emergency departments really be screening for hypertension?

J Lee

Fleming et al., in this issue of the EMJ, present further evidence that hypertension identified in the emergency department (ED) should not simply be dismissed as secondary to pain, anxiety or “white coat” effect. Their finding that 28% of patients with “minor injuries” were hypertensive should not surprise, as the British Society for Hypertension reports that 42% of 35–64 year olds in the UK have hypertension.2 Clearly, we can screen for hypertension in the ED but should we do so?

Few would disagree that tight control of blood pressure across the UK population would prevent a significant number of deaths from myocardial infarction and stroke. Individually, however, hypertension is controlled in only a third of treated patients.3 In this study, only 40% of patients with identified hypertension returned for follow up and of these it is not known how many subsequently registered with a general practitioner (GP) and complied with medication. Fleming et al argue that for many patients (particularly in inner cities) the ED is their primary contact with health services and that without screening their hypertension would otherwise remain unidentified. Patients with no fixed abode would be expected to fall into this category, but hypertension was not identified in anyone from this sub-group.

Screening is not new to the ED. In fact, we have a duty to screen for conditions that may be presented to the ED rather than the GP, particularly where identification may immediately prevent further injury, such as in cases of intimate partner violence and non-accidental injury. A recent study from the authors’ own centre4 showed that screening and counselling of patients presenting to the ED with conditions associated with alcohol misuse resulted in a clear reduction in use of the ED by the same patients in the following 12 months. Both of the above are examples of targeted screening, which is more efficient and cost effective than universal screening but inevitably misses more cases. Although Fleming et al describe their screening as targeted, it is in essence universal screening of all patients assigned a triage category of 3–5. EDs do not have a duty, or the resources, to universally screen but inevitably misses more cases. Although Fleming et al describe their screening as targeted, it is in essence universal screening of all patients assigned a triage category of 3–5. EDs do not have a duty, or the resources, to universally screen for asymptomatic, chronic conditions. Unless such screening can demonstrate an immediate health benefit or reduction in ED attendance, our focus should instead remain on improving our performance of core roles. This study, understandably, cannot demonstrate either benefit.

If money is made available to EDs for targeting hypertension it may be better used to assist patients who are not currently registered with a GP to do so. GPs, for their part, can be relied upon to monitor blood pressure, because, as of April 2004, part of their income has been related to the control of their patients’ hypertension. Furthermore, registration with a GP would allow health care needs other than blood pressure control to be addressed and may reduce future visits to the ED.

Fleming et al have demonstrated that screening for hypertension in the ED is feasible but will not convince all that screening for it in the ED is an effective or efficient use of resources. GP “referral” is the preferred option to address hypertension in hard to target groups.
