Safe staffing for nursing in emergency departments: evidence review

Alejandra Recio-Saucedo, Catherine Pope, Chiara Dall’Ora, Peter Griffiths, Jeremy Jones, Robert Crouch, Jonathan Drennan

ABSTRACT

Objective Getting staffing levels wrong in hospitals is linked to excess mortality and poor patient experiences but establishing the safe nurse staffing levels in the emergency department (ED) is challenging because patient demand is so variable. This paper reports a review conducted for the National Institute for Health and Care Excellence (NICE) which sought to identify the research evidence to inform UK nursing workforce planning.

Design We searched 10 electronic databases and relevant websites for English language studies published from 1994. Studies included reported a direct measure of nurse staffing relative to an activity measure (eg, attendances, patient throughput) or an estimate of nurse staffing requirements. Randomised or non-randomised trials, prospective or retrospective observational, cross-sectional or correlational studies, interrupted time-series, and controlled before and after studies were considered.

Results We identified 16 132 items via databases and 2193 items through manual and other searching. After title/abstract screening (by one reviewer, checked by a second) 55 studies underwent full assessment by the review team. 18 studies met the inclusion criteria for the NICE review, however 3 simulation studies that reported simulated rather than measured outcomes are not reported here.

Conclusions The evidence is weak but indicates that levels of nurse staffing in the ED are associated with patients leaving without being seen, ED care time and patient satisfaction. Lower staffing is associated with worse outcomes. There remain significant gaps and in particular a lack of evidence on the impact of staffing on direct patient outcomes and adequate economic analyses to inform decisions about nurse staffing. Given that an association between nurse staffing levels and patient outcomes on inpatient wards has been demonstrated, this gap in the evidence about nurse staffing in EDs needs to be addressed.

INTRODUCTION

Inadequate staffing levels in hospitals has been linked to excess mortality and poor patient experiences. Safe nurse staffing requires that there are sufficient nurses with the required skills to meet patient needs, and that they are organised and managed in a way that enables them to deliver the highest quality of care possible. Establishing a safe nurse staffing level is a key challenge, notably in the emergency department (ED) where the acuity and quantity of patient demand is highly variable. Demands on EDs nationally and internationally are increasing. In England, the number of patients attending consultant-led 24-h EDs with full resuscitation facilities has risen by approximately 12 per cent. Waiting times in major EDs have also risen: the percentage of patients seen in 4 h or less fell from 93.5% in 2013/2014 to 88.9% in 2014/2015. The number of patients waiting on a trolley for admission increased from 33 909 in the winter of 2010/2011 to 105 770 in the winter of 2014/2015. These increasing demands have implications for safe staffing nursing requirements.

We conducted an evidence review for the National Institute for Health and Care Excellence (NICE) to identify research that could inform nursing staff requirements to support safe care in EDs across the UK. The review followed established NICE methodology for developing public health guidance and while directed towards UK policy, it includes international evidence to inform global debates about safe nurse staffing.

For the purpose of this review, we defined EDs as consultant-led 24-h services with full resuscitation facilities and designated accommodation for Accident and Emergency patients (sometimes referred to in the UK as a ‘Type 1 ED’). The nursing team was defined as those delivering ‘hands on’ nursing care to adults and children, to meet fundamental needs and providing technical care, including medication administration and necessary administrative work. Nurse staffing focused on the size and skill mix (number of registered nurses in proportion to healthcare assistants) of the nursing team relative to the number of patients cared for, expressed as nursing hours per patient day (the number of hours worked by registered nurses and healthcare assistants divided by the number of patient hours over a 24-h period), nurse patient ratios or an equivalent measure.

Our remit, agreed with NICE, was to review the literature reporting studies at department and organisation level to address six questions:

1. What patient outcomes are associated with safe nurse staffing?
2. What patient factors affect nursing staff requirements (eg, case mix and volume, acuity, dependency and other risk factors, including psychosocial complexity and safeguarding, informal (family) carer support, triage score and turnover)?
3. What staffing factors affect nursing requirements including services provided by staff who are not part of the core nursing establishment, division of tasks, models of nursing care (eg, triage, rapid assessment and treatment), nursing experience, skill mix and specialism, transfer duties within the hospital and to external...
specialist units, nursing team management and administration, proportion of temporary nursing staff, and supervision and teaching?

4. What environmental factors affect nursing staff requirements including availability and physical proximity of other units and specialties/services, department size and physical layout and department type (e.g., major trauma centre)?

5. What organisational factors influence nursing staff requirements, including availability of other services or assessment models (i.e., medical assessment units, ambulatory facilities or inpatient ward), crowding, management structures, organisational culture, policies and training?

6. What approaches for identifying nursing staff requirements, including toolkits, are effective, reliable and/or valid and how frequently should they be used?

For all questions we also considered relevant economic evaluations.

METHODS

Search strategy

We searched 10 electronic databases (Embase, CINAHL, CENTRAL, HTA, CDSR, DARE, NHS EED, NHS Evidence, Econlit and Medline) and seven relevant websites (American Nurses Association, Royal College of Nursing, Joanna Briggs Institute, Royal College of Emergency Medicine, Society for Acute Medicine, Faculty of Emergency Nursing, Trauma Audit & Research Network). Internet searches for grey literature and additional citation searching were also undertaken. A list of search terms is provided in the online supplement.

Inclusion criteria

The review covered literature published from 1994. To be included, studies had to report a direct measure of nurse staffing (e.g., numbers of nurses on a shift, nursing hours per day) relative to a denominator based on activity (e.g., attendances, patient throughput) as an independent variable or an estimate of nurse staffing requirements as a dependent variable. We considered randomised or non-randomised trials; prospective or retrospective observational studies; cross-sectional or correlational studies; interrupted time-series; controlled before and after studies. We included research published in English, and undertaken in the Organisation for Economic Co-operation and Development area (as per the NICE remit).

Studies focused on service redesign or reconfiguration, and those which looked exclusively at other members of the multidisciplinary team, including emergency nurse practitioners or advanced nurse practitioners, were excluded. Likewise, we did not examine studies of single specialty EDs (ophthalmology or dental) or non-consultant (attending) led minor injuries units. Advanced nurse practitioners, were excluded. Likewise, we did not examine studies of single specialty EDs (ophthalmology or dental) or non-consultant (attending) led minor injuries units.

Quality appraisal

A quality appraisal checklist based on the risk of bias assessment for cross-sectional studies published by NICE3 which was used in a previous review on safe staffing in acute care settings8 was used to assess risk of bias. Initial screening consisted of rapid exclusion based on title/abstract completed by one reviewer with a random 10% check by a second reviewer. Any disagreements were resolved by recourse to a third independent reviewer.

Studies were rated for internal and external validity separately and corroborated by two researchers.

Search results were downloaded into the reference management software Endnote. Data were extracted on study aims, context/setting, research design, sample size and type, patient/nurse level risk adjustment, intervention, outcomes, conclusions. Summary tables of extracted data were produced and synthesised in a narrative form.

RESULTS

We identified 16,132 items via databases and 2,193 items through manual and other searching. After title/abstract screening (by one reviewer, checked by a second) 35 studies underwent full paper assessment and 18 studies met the criteria and were included in the final review (see figure 1). Three simulation studies that reported simulated rather than measured outcomes are not reported here as we did not have access to details of the primary data collected, analyses and estimated relationships used to develop these simulations.

Figure 2 illustrates the dispersed evidence currently available to inform nurse staffing in ED settings. Some studies looked at more than one outcome; most outcomes were examined in single studies, making it difficult to identify trends or meaningful patterns.

Below we present the evidence provided by the studies structured around the research questions.

Patient outcomes associated with nurse staffing (review question 1)

Nine studies explored the relationship between outcomes and nurse staffing9–17 (table 1). The majority of these (six out of nine studies) were observational studies undertaken in single ED departments, which received between 30,000 and 180,000 patients per year. Seven out of nine studies were completed in the USA. Most of the studies were assessed as high risk of bias, limited on internal (five out of nine) or external validity (eight out of nine). A particular risk of bias associated with many studies was that the relationships reported are influenced by endogeneity (outcomes and staffing levels are influenced by patient need), which could result in attenuated staffing outcome associations or apparent counterintuitive results whereby higher staffing levels are associated with worse outcomes.

Outcomes reported included patient waiting times, time spent in the ED, patients who left without being seen, patient satisfaction, medication errors, time to aspirin or antibiotic administration, and ambulance diversion. The evidence regarding patient waiting times is mixed. However, there is evidence that lower levels of ED staffing are associated with increased levels of
patients leaving without being seen. Studies in the USA found short-staffing of registered nurses to be a predictor of a higher number of patients leaving without being seen (OR 2.4; 95% CI 1.3 to 4.5, p<0.006); the number of nursing vacancies (full time equivalent (FTE)) was strongly correlated with the percentage of patients leaving without being seen (r=0.89, p=0.007) and registered nurses to patient ratio was significantly associated with odds of patients leaving without being seen (OR 6; 95% CI 2.3 to 15.4).

Time spent in an ED bed before discharge or transfer to an inpatient bed was reported to increase when nurse staff was out-of-ratio (ratios defined as 1:1 for trauma resuscitation patients, 1:2 for critical patients, 1:4 for all other ED patients), with 37% longer care time (95% CI 34% to 41%, p<0.001) in two sites combined. Increases in nurse staff skill mix was associated with increased patient satisfaction. Longer lengths of stay for patients in ED were associated with an increase in hospital occupancy rates, additional patients admitted to the wards and the number patients admitted to intensive care unit (ICU) from the ED. No association was found between ED nurse staffing medication errors, time to antibiotics, ambulance diversion or patients’ time in the ED.

Staffing, patient, organisational or environmental factors, and nurse staffing requirements (review questions 2–5)

With regards to other staffing, patient, organisational, and environmental factors affecting nurse staffing requirements, two studies (table 2) explored the introduction of a specialist psychiatric nursing service and absenteeism (staffing), one study explored workload and patient acuity (patient factors) and one explored the association between hospital-wide bed capacity, nursing and physician numbers at hospital level and waiting time (organisational factors). All four studies had significant risk of bias due to limitations in internal validity, and three out of four studies were assessed as having limitations in external validity. There were no studies that provided evidence regarding environmental factors.

A US study about task allocation analysed 63 nursing shifts and found that on average registered nurses spent 25.6% of their time performing direct patient care, 48.4% on indirect patient care, 6.8% on non-registered nurse (RN) care and 19.1% on personal time (meal and toilet breaks, reading, non-patient-related conversation). Personal task allocation varied with increasing direct and indirect patient care, with non-RN care remaining relatively constant, and decreasing personal time.

One UK study assessed the impact of a dedicated specialist psychiatric nurse service on patient outcomes using a before and after cross-over design, assessed as weak for internal and external validity. This staffing intervention had no association with waiting times (hospital 1 p=0.76 and hospital 2 p=0.76), repeat attendances or patient satisfaction levels for people with mental health problems; however, there was evidence of difference of the referral of patients with mental health problems seen by the psychiatric nurse service when compared with the preintervention period. Patients seen by a psychiatric nurse who were recognised as having mental health problems were more likely to be transferred to a mental health unit than admitted to a medical ward (p<0.001), referred to an outpatient clinic (p=0.027) and less likely to be discharged against medical advice (p=0.001). The study found no association with waiting times, repeat attendances or satisfaction levels for mental health patients.

A retrospective observational study assessed as weak in terms of internal and external validity, modelled the impact of changing organisational variables on patient care time (time between being seen by a doctor and being admitted to hospital). This reported that a 1% change in the mean number of nurses at hospital level was associated with a 2.4% fall in ED waiting time and that an increase of 1% in the bed capacity was associated with a 3% fall in waiting time.

We found no studies regarding the influence of environmental factors such as physical layout on nurse staffing requirements.

*Internal/external validity (+, −). The summary bias assessment was completed from a detailed evaluation that considered risk adjustment, data completion and sampling strategy across data sources, outcome types and levels. Ratings were summarised to give a + for some of the assessment criteria fulfilled and conclusions unlikely to change or − for few criteria fulfilled and conclusions likely to change. During quality assessment, no studies were rated ++ indicating that the method was likely to minimise bias or with conclusions unlikely to change.

### DISCUSSION

This review identified a number of outcomes that appear to be associated with nurse staffing levels in ED. While the evidence is not strong, it appears to indicate that levels of nurse staffing in the ED are associated with patients leaving without being seen, ED care time and patient satisfaction. Lower staffing is associated with worse outcomes. We did not find strong evidence that waiting times, medication errors, and the rate of aspirin administration or ambulance diversion are affected by nurse staffing levels. There is conflicting evidence from two weak studies on the association between nurse staffing and time to antibiotics for patients with pneumonia. There was evidence from one study that patients with mental health problems seen by a dedicated psychiatric nurse in an ED were more likely to be transferred to a mental health unit.

At an organisational level, longer lengths of stay for patients in ED were associated with an increase in hospital occupancy, additional patients admitted to the wards and the number patients admitted to ICU from the ED.16 One study21 identified that increases in the number of nurses and doctors, and bed capacity in a hospital was associated with a reduction in the average waiting time in ED. Another study20 showed that as workload increased, direct and indirect patient care also increased while personal time decreased. There is no evidence of the effectiveness of toolkits for identifying staffing requirements although there is a suggestion that the JDT can be used to determine nursing workload in EDs.22

This review has some limitations. The focus and scope of the review was determined by the remit provided by NICE and was necessarily tailored to the UK policy environment. Nonetheless our findings and conclusions have relevance beyond this context. We limited our search to studies in English, from Organisation for Economic Co-operation and Development countries, and only explored those that reported on the observed associations between staffing levels and patient outcomes. We have not reported on simulation and modelling studies as we did not have access to details of the primary data or relationships used to develop these. However the three simulation studies we examined for the larger NICE review do not alter the conclusions offered in this paper. All the studies reviewed were observational, no randomised controlled trials were identified and this is a significant weakness of study design and therefore of the evidence base.

Furthermore, research exploring associations between staffing levels and outcomes needs to explore thresholds which might
help identify adequate staffing levels, rather than only modelling linear associations. The patient populations and outcome measures varied across the research reviewed, as did the quality of the included studies which makes generalisation problematic. Synthesis of findings was not possible, in part due to the diverse outcomes studied (see figure 2). While clearly no single outcome can fully reflect safe and effective staffing in emergency departments, future research would benefit from a more consistent approach to measurement which may include utilisation (waiting times and left without being seen), safety (e.g. drug administration errors) and measures of staff wellbeing (job satisfaction and staff turnover).

CONCLUSION

There remain significant evidence gaps, notably a lack of evidence on the impact of staffing on direct patient outcomes such as mortality, failure to rescue, never events, time to pain assessment or falls. This is in stark contrast to the evidence base for the association between ward based nurse staffing and patient outcomes, which is large and offers strong evidence that lower nurse staffing levels are associated with higher rates of mortality and failure to rescue in North America, Europe and elsewhere24 25–28 although evidence that this relationship is causal and for relationships with other outcomes remains limited.29 Moreover there is no adequate economic evidence that could inform decision making about nurse staffing in EDs. Given compelling evidence of association between nurse staffing levels and patient outcomes on inpatient wards, further research is urgently needed to guide decision making about nurse staffing in EDs.
