Prehospital management and identification of sepsis by emergency medical services: a systematic review

Daniel Lane,1,2,3 Robbie I Ichelson,4 Ian R Drennan,2,3 Damon C Scales5,6

ABSTRACT

Objective To identify studies describing the accuracy of prehospital sepsis identification and to summarise results of studies of prehospital management of patients with sepsis, severe sepsis or septic shock.

Methods We conducted a systematic review to retrieve studies that evaluated the prehospital identification or treatment of patients with sepsis by emergency medical services (EMS). Two authors extracted data describing the study characteristics, incidence of sepsis among EMS-transported patients, criteria used to identify sepsis and specific treatments provided to patients with sepsis. When possible, we calculated the sensitivity and specificity of EMS provider diagnosis of sepsis.

Results Our search identified no randomised controlled trials and 16 cohort studies. Eight studies described the identification of sepsis, seven described prehospital management or treatment of sepsis and one described both. The most common approach to the identification of sepsis involved applying systemic inflammatory response syndrome criteria or a combination of vital signs, which had sensitivity ranging from 0.43 to 0.86 when used alone or combined with provider impression. Only four studies collected information required to calculate specificity (0.47–0.87). Meta-analysis was not performed owing to significant heterogeneity and an overall low quality of evidence. A few studies described prehospital sepsis treatment—most commonly intravenous fluid resuscitation.

Conclusions The evidence suggests that identification of sepsis in the prehospital setting by EMS providers is carried out with varied success, depending on the strategy used; however, high-quality studies are lacking. Relying on provider impression alone had poor sensitivity, but some moderate-quality evidence supporting structured screening for sepsis with vital signs criteria demonstrated modest sensitivity and specificity. Additional research to improve diagnostic accuracy and explore improvements in EMS management is needed.

INTRODUCTION

Severe sepsis is associated with a high morbidity and mortality rate and remains the most common cause of death among critically ill patients.1 To manage this disease effectively, early recognition and prompt treatment are recommended.2 Although the use of a protocol for treatment of sepsis has recently been questioned,3 it is widely accepted that early recognition and intervention are essential to achieving good patient outcomes.4

In modern healthcare systems, emergency medical services (EMS) practitioners are often the first healthcare providers to attend to patients with life-threatening injuries and illnesses, including sepsis. EMS practitioners can provide a variety of critical interventions before the patient arrives at hospital. For many time-sensitive health problems, including acute myocardial infarction, trauma, stroke and cardiac arrest, these critical interventions have been shown to improve patients’ chances of survival and improve outcomes.5–7 More patients with sepsis are transported by EMS to hospital than patients with acute myocardial infarction or stroke and almost half of all patients admitted to hospital with severe sepsis are brought to the emergency department (ED) by the EMS.8 This suggests that EMS practitioners might also be able to provide time-sensitive treatments for patients with severe sepsis. However, targeted evidence-based treatments of sepsis have seldom been adopted within EMS systems.9

Despite this opportunity for early recognition and intervention before arriving at the ED, little is known about practice and research in this area. A comprehensive summary would allow researchers to have a better understanding of the current state of knowledge and areas where further study is required. Therefore, we conducted a systematic review of the literature to identify studies describing the accuracy of prehospital sepsis identification...
and to summarise results of studies of prehospital management (ie, patient characteristics or interventions) for patients with severe sepsis or septic shock.

METHODS
We conducted a comprehensive literature search of the Medline, EMBASE, CINAHL and Cochrane Library databases for all available years until October 2015 to identify studies describing the accuracy of prehospital sepsis identification or potential prehospital sepsis treatments. We combined the following search terms with appropriate synonyms and wildcards: (1) sepsis (“septic”, “infection”) and (2) Emergency Medical Services (“paramedic”, “out-of-hospital”, or “prehospital”) (see online supplementary data). Two authors (DL and RII) independently reviewed the titles and abstracts to identify all relevant English original research studies. Any study flagged by either author as potentially relevant underwent full text review and disagreements were resolved by consensus. We also conducted an independent hand search of the bibliography of all included studies to identify any potentially relevant studies not captured in our search. All original research studies that described the identification or treatment of patients with sepsis in the prehospital setting were included. Studies that were only reported as abstracts were not included.

Retrieved studies were sorted into two groups: studies that examined identification of patients with sepsis by EMS practitioners or those describing prehospital management or treatment of patients with sepsis. We abstracted data describing general study characteristics, incidence of sepsis among EMS-transported patients, tools or characteristics used to identify sepsis and specific management or treatments provided to patients with sepsis. When possible, we calculated the sensitivity and specificity of EMS practitioner diagnosis of sepsis using the available data. The quality of included studies was assessed using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology.10

RESULTS
Our search identified 3885 unique publications, of which 16 were retained after a full-text review. Of the included studies, eight described the identification of sepsis in the prehospital setting, seven described prehospital management or treatment of patients with sepsis and one described both (figure 1). Agreement between reviewers was moderate (κ=0.56) at the abstract review stage but excellent at the full-text review stage for final article inclusion (κ=1.0).

Characteristics of the included studies are summarised in table 1. Studies were primarily conducted in single centres (n=12/16) and in the USA (n=12/16). Identified studies used a cohort study design (n=16/16) with data collected using chart review in the majority (n=13/16).

Quality of evidence
Among studies evaluating prehospital identification of sepsis, the overall quality of evidence was low for studies using provider impression alone for identification and moderate for studies using vital signs (table 1). The quality of evidence for studies describing the management of patients by EMS varied considerably (table 1). A common limitation of included studies was a risk of selection bias due to retrospective selection of patients based on the in-hospital diagnosis of sepsis and a lack of blinded comparison of the EMS providers’ identification of patients with sepsis and the reference standard that was used for diagnosing sepsis. Combining results across studies using meta-analysis (ie, for incidence, sensitivity and specificity) was therefore deemed inappropriate based on the overall low quality of evidence and high degree of heterogeneity.

Incidence of sepsis
Overall, the incidence of sepsis ranged from 1% to 8% among patients transported by EMS (table 1). The severity of disease among this cohort of transported patients with sepsis was high, with the proportion who were subsequently admitted to hospital ranging between 40% and 60% (n=3 studies).8 11 12

Identification of sepsis
Abnormal vital signs were the most commonly applied criteria for identifying patients with sepsis, with four of nine studies considering vital sign abnormalities commonly used within the framework of severe inflammatory response syndrome (SIRS) criteria,8 13-15 three studies considering vital signs including some SIRS criteria within a structured screening tool16-18 and two studies considering EMS provider identification alone.12 19 (table 2). The primary vital signs considered in seven studies were temperature, heart rate and RR. Additional, clinically relevant criteria considered included systolic or mean arterial BP (n=5), GCS (n=3), oxygen saturation (n=2), blood glucose level (n=1), in-hospital lactate (n=1), or abnormal in-hospital white blood cell count (n=1). ED physician diagnosis of sepsis indicated by ED charting or the International Statistical Classification of Diseases and related health problems (ICD) codes for sepsis or infection were the most commonly used reference standard for the definitive diagnosis of sepsis (eight of nine studies).

Sensitivity and specificity of prehospital sepsis identification
There was considerable variation in the calculated sensitivity for EMS identification of sepsis and the index tests that were applied to recognise sepsis (table 2). Variability in the criteria considered and parameters for classifying these criteria as abnormal (eg, RR >20 vs RR >36) limited our ability to perform a meta-analysis (figure 2). EMS provider impression alone was investigated in six studies, with five studies describing very poor sensitivity (0.1–0.31) and one describing modest sensitivity.
overall mortality as the outcomes.20 Through cohort studies (table 3); these focused on maintenance of BP conventional studies of EMS treatments of sepsis. The specific criteria and management by EMS providers.20

- Guerra et al14 To evaluate EMS provider identification of severe sepsis using a screening tool
- Polito et al17 To develop an EMS screening tool for identifying severe sepsis
- Seymour et al8 To describe the incidence of severe sepsis seen in the prehospital setting
- Studnek et al12 To determine the effect of prehospital treatment on the time to definitive sepsis treatment
- Sufoletto et al15 To evaluate EMS provider impression and physiological measures on the identification of patients with severe infection
- Wallgren et al16 To validate prehospital screening tools for sepsis against provider impression

**Prehospital care**

Our search identified no randomised controlled trials or interventional studies of EMS treatments of sepsis. The specific treatments delivered by EMS providers were described in three cohort studies (table 3); these focused on maintenance of BP through fluid administration, with time to achieve BP targets, or overall mortality as the outcomes.20–22 The remaining cohort studies included (n=5) described general management approaches, transfer characteristics or potential prehospital predictors of patient outcome (table 3).11 19 23–25 EMS provider management of patients with sepsis was associated with extended on-scene times (one study, mean 43 min).25 Patients who received intravenous fluids from the EMS during this time, however, had significant reductions in their odds of death according to one cohort study (OR=0.46; 95% CI 0.23 to 0.88).20 Notably, three studies reported that only limited support of BP by EMS providers (in <50% of these patients) occurred despite the measurement and documentation of hypotension.20–22 The variability in studied treatment strategies and limited number of studies precluded any formal meta-analysis.

**DISCUSSION**

We conducted a comprehensive and systematic review of the available literature describing prehospital identification or management of patients with sepsis and retrieved only observational studies and no randomised controlled trials. Our review shows that sepsis is a common condition for EMS patients, with an estimated incidence ranging from 1% to 8% among EMS-transported patients. However, only a few studies of moderate quality have evaluated the accuracy of prehospital identification of sepsis, and randomised controlled trials describing potential treatment strategies are lacking.

Our review provides the first comprehensive review of the identification and management of patients with sepsis by EMS providers in the prehospital setting. The most common approaches applied by EMS providers to identify sepsis are a combination of SIRS criteria or screening tools that include aspects of inflammation, hypotension, altered mental status, and reduced oxygen saturation. There are several challenges associated with sepsis identification in the prehospital setting, including the rapidly changing clinical status of patients and the lack of standardised criteria for sepsis diagnosis. Further research is needed to develop effective and reliable tools for prehospital sepsis identification to improve patient outcomes.

of SIRS. Our findings suggest that EMS providers’ abilities to correctly identify this condition vary considerably depending on the criteria used, but use of a structured screening strategy, such as a tool, has much better accuracy than provider impression alone. Our review also highlights the need for the validation of prehospital sepsis screening strategies with improved sensitivity and specificity for recognition of sepsis and to ensure that prehospital screening for sepsis does not result in harm (ie, inappropriate treatment).

Although few studies have demonstrated an association between early EMS recognition or treatment of sepsis and improved patient outcomes, we identified several studies that show earlier initiation of treatment within the ED and a trend towards earlier achievement of resuscitation goals (table 3). Despite shorter transport times in some urban settings, EMS providers are often the first contact for these patients with a health professional, who remains with them throughout the transport and transfer of care to hospital staff. This offers an important opportunity for early recognition and notification of emergency staff and for the initiation of treatments in the prehospital setting. Further study examining a larger population of patients from settings where transport times vary may demonstrate a greater benefit for EMS recognition and treatment of this disease.

Fluid resuscitation of patients with sepsis by EMS providers was the most commonly described intervention and was
reported to reduce the time to achieving BP goals for these patients after hospital arrival and decrease their odds of death.20 22 Despite this finding, only a small fraction of these patients were fluid resuscitated by EMS providers, often <50% of patients with severe sepsis (table 3). However, these studies often lacked comparison groups, or were vulnerable to a risk of confounding by indication and selection bias. Further investigation with randomised controlled trials is required.

Our study has several limitations. Despite our comprehensive literature search, we were unable to find studies of high methodological quality evaluating EMS identification. Notably, retrieved studies were characterised by a risk of selection bias as many had restrictive inclusion criteria and identified patients retrospectively. Another limitation of the studies included was a lack of systematic screening of patients transported by EMS, which precluded estimation of specificity and false negative rates for prehospital sepsis diagnosis for many studies. This limitation was partially because the objectives of the studies identified did not align with the objective of this review. We excluded conference abstracts and non-English studies, leaving a potential gap in the science of prehospital sepsis treatment were missed. Most of the studies included were conducted in the USA, which may limit the generalisability of our findings to other prehospital systems of care. Finally, future research exploring the accuracy of prehospital identification should strive to include a complete and representative sample of all EMS-transported patients to reduce the risk for selection bias.

**CONCLUSION**

In summary, EMS providers will commonly encounter patients with severe sepsis when responding in the prehospital setting. However, the available evidence suggests that the identification of sepsis by EMS providers is done with varied success, depending on the strategy used. Relying on provider impression alone had limited success, whereas applying a structured screening strategy showed reasonable success. However, only a few studies of moderate quality have assessed the ability of EMS providers to identify patients with sepsis, and treatments have seldom been explored. Additional research to improve diagnostic accuracy and explore improvements in EMS management is needed.
